Receptors can play an active role during cell entry, initiating the translocation of the genome from the virus particle to the cytosol. Virus binding to receptor molecules can mediate conformational changes in the particles that initiate genome uncoating, which require multivalent receptor engagement. In enveloped viruses, receptors also facilitate the engagement of co-receptors for membrane fusion. Mature virions and virus proteins are susceptible to temperature-induced motions, which generate metastable virus conformations. The receptors can thus sustain certain virus states primed for uncoating at physiological temperatures without external energy. In line with this, it is accepted that certain receptors function as catalyzers, maintaining metastable virus structures that facilitate genome release, with or without involvement of other host factors such as the low endosomal pH.

Receptor-mediated endocytosis

Using receptor molecules, viruses can subvert the endocytic machinery to gain access into the cell using a variety of mechanisms. In addition, virus-mediated receptor crosslinking can trigger signaling events that regulate endocytosis. Certain receptors move to endosomes and ferry bound viruses to intracellular compartments, where the viruses come across a pH gradient (7 to 5) that in many cases initiates genome translocation. Mild low pH (5.5–6.0) is a relevant trigger of membrane penetration events, such as the fusion of virus and cell membranes that commonly occurs at endosomes. Even viruses that do not need low pH for entry penetrate in endosomes. Others use endocytosis to access entry receptors located in the endolysosomal system.

The Identification of Virus Receptors

Since the virus receptor is a cell-specific molecule involved in cell entry, the identification of the receptor requires demonstrating that a cell becomes susceptible to a virus upon expression of the receptor. In cases where several receptors are required for cell infection, detecting virus attachment can be used to identify tentative virus receptors.

Several approaches have identified virus receptors based on the detection of virus binding, which can require labeled viruses or antibodies (Abs) against virus proteins. Indirect methods either use Abs that target the receptor, proteases or glycosidases to block binding. Direct methods use virus proteins to identify and/or purify cell surface receptors. Recent advances in glycan microarray screening technology have accelerated the identification of glycan receptors for many viruses. Once the attachment molecule is identified, its ability to support virus cell entry or infection is assessed. Genetic methods are based on the transformation of a non-susceptible cell with DNA encoding the protein. For these methods, cDNA libraries from permissive cells are used. Following expression on the cell surface, the acquisition of a virus binding phenotype is tested, perhaps combined with the demonstration of specificity by the inhibition with monoclonal Abs. As an example, a novel CRISPR-Cas9 based screen has been recently followed to identify an alphavirus receptor. Typically, a combination of the approaches outlined above is necessary to unequivocally demonstrate the identity of a virus receptor. Multiple confirmatory approaches are required as each technique has inherent uncertainties.

Structural knowledge on the interactions between viruses and protein receptors is available for many viruses. In some cases, such knowledge has led to sophisticated models involving conformational changes in viral proteins and receptors as a result of receptor engagement. By contrast, the role of protein-glycan interactions in viral attachment and entry is less well understood, in part because cell-surface glycans form a heterogeneous mixture of complex carbohydrate moieties that are difficult to classify. For many viruses, only fragments of glycan receptors such as terminal sialic acid (Sia), sialyllactose, or sulfated oligosaccharides have been identified, and it is entirely unknown to which cell-surface glycoconjugates these fragments belong. As a consequence, it is largely unclear how glycan-binding impacts post-attachment events in the life cycle of most viruses, such as cell entry and viral uncoating.

Rather than aim to provide a complete catalog of viruses and receptors, the focus of this article is to use key examples to illustrate cell surface receptor families engaged in virus cell entry. The examples used below illustrate a range of different types of viral receptors, either carbohydrates or proteins, and those in which multiple receptors and co-receptors have been implicated. Due to their pivotal role in determining tissue and host tropism, and hence influence on pathogenesis, particular efforts have been made in identifying receptors for important human and animal virus pathogens, some of which are described here.

Glycan Receptors, Interactions with Viruses

Many viruses attach to glycan structures during the first step of an infection (**Fig. 1**). In some cases, the binding of carbohydrates can prime the virus particle for conformational changes. Glycan-virus interactions also affect other aspects of viral infections, such as the exit of virus particles from host cells and the efficiency of viral spread, illustrated by influenza viruses. For most viruses, the biological and medical consequences of the glycan-virus interplay, such as viral tropism, cell entry and pathogenesis, are not well understood. The use of glycans as biological tools or as targets for drug discovery has likewise been hindered by the inability to easily synthesize, sequence and study their biological functions. Below, we review examples of viruses binding to sialic acids, histo-blood group antigens (HBGAs) and glycosaminoglycans (GAGs) (**Fig. 1**).

Fig. 1 Glycans as viral receptors. Host- and cell-specific variants of sialic acids (**A**), neutral oligosaccharides (**B**) such as histo-blood group antigens (HBGAs) and glycosaminoglycans (GAGs) (**C**) used as receptors/attachment factors by many viruses. Examples of virus families with members that are known to interact with one or more glycan types are indicated in the respective overlapping ellipses of the Venn diagram.

A. The most common form of sialic acid in humans, N-Acetylneuraminic acid, is shown in the α -conformation. This monosaccharide often caps N-, O-glycans and glycolipids (R), which are attached via different glycosidic linkages to position C2. Various modifications can occur at carbon positions C4, C5 and C7-C9 (marked with red spheres). **B.** Schematic representation of the type 2 core antigen, which is part of the ABO blood group determinants on N- and O-glycans. R: heterosaccharide core attached to a glycoprotein. **C.** Heparan sulfate (HS), an example for GAGs. HS domains along the oligosaccharide chain usually vary in their modification contents by N-sulfation/N-acetylation at carbon positions C2 and C6 of the hexosamine, and by sulfation at C2 of the uronic acid.

Fig. 2 Viruses engage different sialic acid conformations. Examples of how closely related (or identical) viruses engage α 2,3-linked (left column) or α 2,6 linked (right column) sialylated glycans. **A, B.** Close-up views of the glycan-binding sites of avian (PDB ID 2WR2) and human (PDB ID 1RVZ) influenza virus haemagglutinins bound to the LSTa and LSTc glycans, respectively. **C, D.** Close-up views of the glycan binding sites of polyomavirus VP1 proteins (PDB IDs 3BWR for the SV40-GM1 complex and 3NXD for the JCPyV-LSTc complex). The GM1 glycan terminates in α 2,3-linked sialic acid. **E, F.** Enterovirus D68 structures bound to α 2,3-sialyllactose (PDB ID 5BNP) and α 2,6-sialyllactose (PDB ID 5BNO). In all panels, the viral capsid proteins are shown in surface representation, with glycans and contacting protein residues represented with sticks. Sialic acid residues are shown in color, while the remaining glycan chains are gray. Hydrogen bonds and salt bridges between glycans and proteins are indicated with black dashed lines.

Sialic Acid Receptors

Cell-surface glycans featuring terminal sialic acids can serve as functional receptors for enveloped and nonenveloped viruses (Fig. 1). Sialic acids are ubiquitously expressed in higher vertebrates and are attached at the terminal ends of *N*- and *O*-glycans as well as glycolipids. The most common sialic acid in humans is α 5-*N*-acetylneuraminic acid (Neu5Ac). Sialic acids are usually connected via α 2,3 or α 2,6 glycosidic linkages to galactose (Gal) or *N*-acetylgalactosamine (GalNAc), but they can also be linked to one another through α 2,8 or α 2,9 linkages. Here, we review the sialic acid-binding strategies of influenza viruses, polyomaviruses, and enteroviruses (Fig. 2).

Influenza Viruses

Influenza viruses are segmented, single-stranded RNA viruses in the orthomyxovirus family that infect mammals and birds; they can be classified into types A, B and C. Influenza A and B viruses primarily cause serious disease in humans, as evidenced by yearly

outbreaks worldwide. Influenza viruses engage α 2,3- and α 2,6-linked Neu5Ac attached to a penultimate galactose of the glycan receptor. The trimeric viral hemagglutinin (HA) initiates cell contact by binding to Neu5Ac. The carbohydrate-binding site of HA is conserved in all influenza subtypes and located in a shallow groove near the top of the protein. The orientation of Neu5Ac and its interactions with HA are also conserved among influenza virus strains (**Fig. 2(A)** and **(B)**). Nonetheless, the context of sialic acids in the recognized glycan structures varies. Avian influenza virus HA primarily binds to α 2,3-linked Neu5Ac in a glycan that typically assumes an elongated *trans* conformation (**Fig. 2(A)**), whereas human influenza viruses preferentially attach to α 2,6-linked Neu5Ac in an oligosaccharide with a folded-back *cis* conformation (**Fig. 2(B)**). Structural analysis of avian H5 and H7 strains demonstrated that an HA point mutation leads to an increased affinity for α 2,6-linked sialic acid.

Glycans containing α 2,3-linked Neu5Ac display restricted conformational freedom and form a cone-like glycan structure. Conversely, glycans containing α 2,6-linked sialic acid have greater conformational flexibility, and such glycans assume umbrella-like shapes. The link between sialic acid and galactose in the receptor molecules defines the glycan topology and thus determines the affinity of a given HA.

Polyomaviruses

Polyomaviruses (PyVs) form a rapidly expanding family of small, non-enveloped dsDNA viruses that include several recently discovered human pathogens and cause a range of diseases in humans, including cancer. PyV capsids comprise 72 VP1 pentamers, termed capsomers. Each capsomer has five low-affinity glycan binding sites, facilitating multivalent binding to receptors and high avidity interactions that are critical for PyV targeting to the endocytic pathways and cell entry. Typically, VP1 binds terminal Neu5Ac as well as neighboring sugar residues in its glycan receptors, whereas the human BK (BKPyV) and JC (JCPyV) polyomaviruses engage the ganglioside GT1b and the lactoseries sialyl tetrasaccharide c (LSTc), respectively.

Some PyVs share a common binding site for sialic acid, with largely conserved contacts to the protein capsid. This is for example the case in simian virus 40 (SV40) and JCPyV, which bind sialic acids in the same orientation and with largely identical contacts (**Fig. 2(C)** and **(D)**). Nevertheless, glycan microarrays have shown that the two viruses are able to specifically bind to only one sialyloligosaccharide, and specificity for this glycan is encoded by a small number of residues that lie outside of the sialic acid binding pocket, and that make contacts with other components of the receptor. In SV40, several residues contact the terminal Gal residue in the branched GM1 glycan, which features an α 2,3-linked sialic acid (**Fig. 2(C)**). The monosaccharides Neu5Ac, GalNAc and Gal are arranged in a more linear conformation in this glycan. In JCPyV, the side chain of Asn123 contacts the acetyl group of the third monosaccharide, GlcNAc, ensuring specific recognition of the L-shaped pentasaccharide receptor LSTc, which contains α 2,6-linked sialic acid (**Fig. 2(D)**). As in influenza viruses, the longer α 2,6-linkage allows a L-shaped receptor conformation that enables the interactions with Asn123.

Enteroviruses

Enteroviruses (EVs) are very common and cause infections with a diverse array of clinical features. They belong to the picornavirus family and form non-enveloped, small (22–30 nm) icosahedral particles that encase an RNA genome. Although most members cause gastrointestinal and respiratory illnesses, often in children, some EVs have unique disease associations, including acute hemorrhagic conjunctivitis (AHC) caused by EV-70 and the group A coxsackieviruses A24 (CVA24). Recent structural studies on the EV-D68 and a CVA24 variant (CVA24v), show that both viruses engage sialylated glycan receptors, albeit in different regions of the capsid.

Interestingly, both EVs preferentially bind α 2,6-linked sialic acid, but for different reasons. In the case of EV-D68, specificity can be attributed to the architecture of the binding site. Binding of the linear α 2,3-linked sialoglycans would introduce steric hindrance, while the binding site can easily accommodate the bent α 2,6-linked sialylated structures (**Fig. 2(E)** and **(F)**). In CVA24v, the structures only provide details about the sialic acid moieties, while the remaining saccharide chains are not visible in the electron density maps. However, molecular dynamics simulations show that the α 2,6-linked glycans are more flexible and can establish more contacts with the viral capsid, suggesting a reason for the virus selection of this linkage.

Histo–Blood Group Antigen Receptors

The wide range of glycans used for attachment by viruses also includes the histo-blood group antigens (HBGAs) (**Fig. 1**), which are complex carbohydrates expressed on the surfaces of red blood and epithelial cells. HBGAs are also found in soluble form in mucosal secretions. The HBGA phenotypes in humans are polymorphic and complex, and they are associated with multiple gene families. HBGAs can serve as attachment factors for noroviruses and rotaviruses.

Noroviruses

Human noroviruses are non-enveloped, positive-sense RNA viruses of the calicivirus family that interact with HBGAs (**Fig. 1**) and cause acute gastroenteritis outbreaks worldwide. Binding studies with norovirus virus-like particles (VLPs) and specific Abs to blood-group antigens, soluble blood-group antigens or glycosidases, have confirmed a role for HBGAs in norovirus attachment. Based on the capsid gene sequence, noroviruses are divided into seven genogroups (GI to GVII) and over 30 genotypes. Their capsids are formed by a single protein, which can be divided into shell (S) and protruding (P) domains. The P domain is highly

Fig. 3 The receptor-binding region on the rotavirus spike VP8* protein accommodates different glycan types. Panel **A** shows a view into the ligand-binding site of porcine rotavirus CRW-8 VP8* bound to the GM3 glycan (PDB ID 3SIT), and panel **B** shows the same view for human rotavirus strain HAL1166 VP8* bound to a tetrasaccharide corresponding to the terminal structure of A-type HBGA (PDB ID 4DS0). The VP8* structures are shown in semitransparent surface representation, and key contact residues and bound glycans are depicted as sticks. Carbon atoms of GM3 residues that interact with the protein are colored in orange and those in A-type HBGA residues in yellow; unbound residues gray. Direct hydrogen bonds between VP8* and glycans are black dashed lines, to indicate the different classes of the two glycans.

variable, but contains determinants for cell attachment and entry. Capsid proteins from distinct human norovirus strains show different HBGA binding patterns, suggesting that capsid-glycan interactions are major determinants for norovirus evolution. Host susceptibility to specific human norovirus strains and pathogenesis are likely influenced by genetically controlled expression of different HBGA structures on host cells.

Rotaviruses

Rotavirus infections are a leading cause of severe, dehydrating gastroenteritis in young children. Despite the global introduction of a rotavirus vaccine over a decade ago, rotavirus infections still result in >200,000 deaths annually worldwide. A human rotavirus was recently found to bind HBGAs, and this is of particular interest as most known rotaviruses had been reported to engage sialylated glycan receptors. In this study, a combination of glycan microarray screening and crystallographic analysis demonstrated that the attachment protein VP8* from the human P[14] rotavirus strain HAL1166 specifically binds HBGAs at the same site that interacts with sialic acid in other rotavirus strains (Fig. 3). The VP8* protein of HAL1166 rotavirus exhibits subtle modifications in its binding site that lead to inability to bind sialic acid and engagement of HBGAs. The specificity switch is particularly relevant, as more recent analyses have shown that the globally dominant human rotavirus genotypes bind HBGAs; in fact, they recognize a subset within the HBGA family that represents the most abundant glycans in the intestinal epithelial cells.

Glycosaminoglycan Receptors

The third class of virus glycan receptors or attachment factors is the polyanionic GAGs (Fig. 1). They are linear glycans assembled with β 1,4-linked disaccharide blocks, which contain an N-acetylated or N-sulfated amino sugar (GlcNAc or GalNAc) linked to either a uronic acid (glucuronic or iduronic acid) or galactose (Fig. 1). GAGs are components of proteoglycans and thus are in the extracellular matrix as well as in the cell membranes of most eukaryotic tissues.

Given their prominent location on the surface of cells, it is not surprising that a large number of viruses have been reported to use GAGs as attachment or entry receptors. However, our understanding of the rules underlying virus-GAG interactions at the molecular level remains limited because of few reliable high-resolution structures of viral proteins in complex with GAGs. Furthermore, observations that several viruses, such as foot-and-mouth disease virus (FMDV), undergo cell culture adaptation related to an increased binding to HS without any selective pressure, questioned the utilization of HS by clinical, non-culture-adapted strains. Finally, it is also becoming clear that GAGs act as decoy receptors for some viruses.

The picornavirus FMDV was one of the first examples for which high-resolution studies of GAG-virus interactions became available. Crystal structures of the human papillomavirus (HPV) capsid protein L1 bound to oligomeric heparin have more recently been reported. However, our inspection of the available coordinates and electron densities (PDB ID 3OAE and 3OFL) shows that the ligands are not well defined in the complexes, likely because of low occupancies. The reported contacts between the HPV L1 proteins and heparin must therefore be treated with caution. A more recent cryo-EM reconstruction of the entire HPV capsid bound to heparin shows that the glycans bind to recessed regions between the L1 pentamers. The resolution of the structure is however not sufficient to assign atomic-level interactions. A number of low-resolution structures of complexes with GAGs or analogs have also been determined for different adeno-associated viruses.

Fig. 4 The IgSF Nectin-1 in cell adhesion and virus recognition. **A.** Homophilic nectin-1 cell adhesion interactions. Ribbon diagram of the extracellular nectin-1 region with the three Ig-like domains (D1-D3), which forms a dimer in the crystal structure (PDB ID 3U83). The interacting N-terminal domains (D1) in the homophilic dimer are blue and cyan, with the GFCC'C'' β -sheet engaged in the adhesion interaction labeled. **B.** The HSV gD glycoproteins bound to nectin-1. Ribbon diagram of the gD-nectin complex structure (PDB ID 3U82), with the gD Ig-like domain (magenta) bound to the N-terminal D1 (cyan) of nectin-1. The virus protein interacts with the GFCC'C'' β -sheet of the membrane distal D1.

Glycan-Based Antiviral Strategies

To date, very few examples for antiviral strategies that exploit knowledge about virus-glycan interactions exist. The best-known of these are probably the influenza virus inhibitors oseltamivir and zanamivir, which target the viral neuraminidase by mimicking host glycan structures. Both compounds act as inhibitors of influenza neuraminidase, and prevent the emergence of progeny virions from infected cells. Additional examples include recently developed potent trivalent glycan-based inhibitors of some human adenoviruses, as well as multivalent entry-inhibitors against norovirus infection. In these cases, the inhibitors simultaneously target several glycan-binding sites on the viral capsid with high affinity, efficiently blocking attachment. These studies demonstrate the general feasibility of designing glycan receptor-based viral inhibitors.

Protein Receptors, Interactions With Viruses

Immunoglobulin Superfamily Proteins

Perhaps reflecting their relative abundance at the cell surface, proteins belonging to the immunoglobulin superfamily (IgSF) are implicated in the cell entry of many viruses. The IgSF comprises numerous cell surface proteins, most of which function as cell adhesion molecules (CAM). They are type I membrane proteins with concatenated Ig-like domains at the extracellular region, and viruses commonly recognize the membrane-distal, N-terminal domains (Fig. 4). The Ig fold has two β -sheets bridged by a conserved disulfide bond, although some domains contain additional disulfides. They are classified in different structural sets according to the number of β -strands in each of the two β -sheets.

The IgSF proteins can be grouped in subfamilies based on structure-function similarities. Members of the Nectin and Nectin-like (Necl) subfamilies mediate cell entry of poliovirus (PV), alphaherpesviruses and measles virus (MV). The nectins contain three (D1 to D3) tandem extracellular Ig-like domains (Fig. 4); the N-terminal D1 has an Ig-like variable (IgV) fold, whereas D2 and D3 belong to the constant (C2) Ig set. Nectins mediate homophilic and heterophilic cell adhesion interactions in different tissues. Cell-cell and virus-cell interactions similarly engage the GFCC'C'' β -sheet in the nectin D1 (Fig. 4).

The PV receptor (PVR, CD155), also known as Necl-5, was the first nectin described as a virus receptor. Subsequently, poliovirus receptor-related proteins (PRR) were identified as alphaherpesviruses entry receptors. PRR-1 or Nectin-1 is the entry receptor of herpes simplex virus (HSV) 1 and 2. Nectin-2 functions also as the receptor of certain HSV variants, whereas Nectin-4 is an epithelial cell MV receptor, necessary for movement across the airway epithelium and transmission to new hosts. MV also uses another IgSF member, signaling lymphocyte-activation molecule (SLAM), to initiate the infection in lymphoid cells.

Other cell surface IgSF proteins bearing N-terminal virus-binding IgV domains function as virus receptors: The T-cell specific CD4 protein for HIV-1, the coxsackievirus and adenovirus receptor (CAR), junctional adhesion molecule-A (JAM-A) for reovirus, CD300f for norovirus, carcinoembryonic antigen-like cell adhesion molecule-1 (CEACAM-1) for coronavirus, the Hepatitis A virus cellular receptor-1 (HAVcr-1 or TIM-1), etc. In these receptors, the GFCC'C'' β -sheet is engaged in virus binding. Nevertheless, the virus-binding domains in

Fig. 5 The picornavirus "canyon" in receptor recognition. **A.** Surface representation of the poliovirus (PV) particle (PDB ID 1ASJ). Numbers indicate location of the icosahedral two-, three- and five-fold axes. Two capsid biological protomers are shown with the VP1 (blue), VP2 (green) and VP3 (red), and the canyon region at the interprotomer junction marked with arrows. **B.** IgSF receptors bind to the canyon. Top: Scheme of the PVR and ICAM-1 picornavirus receptors, with the extracellular domains (D) outlined and the N-terminal virus binding D1 colored. Transmembrane (TM), n and c-terminus labeled. Bottom: Representation of the PV and CAV cryo-EM structures bound to PVR (PDB ID 3J8F) and ICAM-1 (PDB ID 6EIT), respectively. Lateral view of the canyon region, with the virus proteins colored as in A. Ribbon and surface representations of the receptor domains and the main virus binding motifs labeled: GFCC'C'' β -sheet in PVR D1 and the BC and FG loops in ICAM-1. **C.** Frontal view of the canyon in the superimposed structures. Surface (gray) and ribbons representations of the virus and the receptors, respectively. **D.** Canyon-binding receptors catalyze picornavirus uncoating. The endothermic canyon-receptor interaction generates high energy (ΔH) virus-receptor (V-R) complexes with an expanded capsid at physiological temperature, which assists RNA exit and accelerates uncoating. Receptor binding lowers the activation energy (E_a) of the virus uncoating process (vertical thin arrows): $E_aV-R < E_aV$. Ve-R: Empty complexes.

other IgSF members such as intercellular adhesion molecule-1 (ICAM-1), a rhinovirus receptor, do not belong to the V set and its narrower conformation facilitates binding into a recessed virus surface (see below). In the recently identified Mxra8 alphavirus receptor, the two virus-binding IgV domains of Mxra8 arrange head-to-head, are disulfide bridged and contain the first β -strands swapped.

Even though IgSF protein structures are similar, viruses recognize specific molecular features in the Ig-like domains, which determine the virus-receptor specificity.

Virus interactions with IgSF receptors

PV, the causative agent of paralytic poliomyelitis, uses an IgSF member for cell entry. Murine cell expression of PVR renders them fully permissive for poliovirus infection, and is the basis for the generation of PVR-transgenic mouse lines for neurovirulence studies. PV is a representative member of the picornavirus family, genus enterovirus; it is a non-enveloped virus with an icosahedral capsid that encloses a positive-sense single-stranded RNA genome (Fig. 5(A)). A depressed capsid surface or canyon surrounding the five-fold icosahedral vertices binds to the membrane distal D1 of PVR (Fig. 5(A) and (B)). Receptor binding initiates a series of irreversible conformational changes in the virus particle, which results in the externalization of capsid polypeptides and the virus genome through the capsid 2-fold axis after expansion. Exit of internal capsid polypeptides occurs in other picornavirus entry intermediates, and it is thought important for capsid-membrane interaction and RNA translocation from the capsid to the cytosol. Indeed, studies with PVR-loaded membrane vesicles showed a membrane pore for viral genome delivery into the cytosol.

Human rhinoviruses (HRV) comprise three species of EVs. The majority of HRVs attach to the membrane-distal Ig-like domain of ICAM-1 (Fig. 5(B)), a member of the IgSF that binds to leukocyte integrins, whereas about 12 HRV serotypes use the low-density lipoprotein receptor (LDLR) and the HRV C viruses use cadherin-related family member 3 as entry receptor. ICAM-1 is also the entry receptor of Coxsackie A virus (CAV). HRV and CAV similarly use the canyon for binding to the N-terminal domain of ICAM-1, such as shown by cryo-EM structures of virus particles in complex with soluble receptors (Fig. 5(B)). The bound ICAM-1 D1 is more perpendicular to the capsid than the PVR D1 (Fig. 5(B) and (C)). The structures indicate that receptor-binding residues are more exposed to Ab neutralization in PV than in CAV or HRV.

Like poliovirus, receptor binding to the canyon initiates conformational changes in picornavirus particles that are considered essential for infection. These canyon-receptor interactions are endothermic and generate metastable complexes with an expanded

Fig. 6 Complement control proteins in virus recognition. **A.** CD46 in complex with the adenovirus (Ad) type 11 knob (magenta) and the complement C3b protein (gray). Surface representation of the CD46 extracellular short consensus repeats (SCR) followed by the serine, threonine and proline rich region and the transmembrane domain. The superimposed CD46-Ad (PDB ID 3O8E) and CD46-C3b (PDB ID 5FO8) complex structures show that Ad and C3b binds to distinct SCR. **B.** DAF binding to the EchoV6 capsid protomer (magenta) and the complement C3b protein (gray). SCR shown as in CD46. The superimposed DAF-EV6 (PDB ID 6ILK), DAF-C3b (PDB ID 5FOA) and DAF alone (PDB ID 1OJV) structures show virus and complement binding to overlapping receptor sites. Structures superimposed based on the receptor molecules.

capsid, a feature of entry intermediates. Capsid expansion occurs by the concerted action of temperature-driven capsid “breathing” and receptor binding, and precedes RNA exit. In certain picornaviruses, capsid expansion in virus-receptor complexes initiates at low pH, with the release of lipid molecules attached to VP1. Canyon-binding receptors mediate uncoating by maintaining the virus capsid in an intermediate open state, which decreases the activation energy of the uncoating process (Fig. 5(D)). Rossmann proposed that the canyon is too narrow to allow the binding of virus neutralizing Abs, thereby allowing the virus to retain a relatively invariant receptor-binding domain in the presence of immunoselection. Nonetheless, structural studies demonstrated that the canyon instead evolved in response to receptor binding requirements and to accommodate structural changes that occur post-binding.

CD4, the primary receptor for HIV, is composed of four Ig-like domains; the HIV envelope glycoprotein (env) binds the most membrane-distal domain (see below). This interaction induces conformational changes in the virus gp120 moiety that mediate attachment to chemokine receptors, which then trigger virus-cell membrane fusion and cell entry. Conformational flexibility, sequence and gp120 glycosylation diversity hide the CD4-binding site (CD4bs) from neutralizing Abs. However, several CD4bs-specific Abs have been identified from HIV-infected elite donors. They exhibit very high breadth and potency, and neutralize over 90% of HIV-1 strains by interaction with highly conserved residues engaged in receptor recognition.

The identification of potent HIV-neutralizing Ab enables prophylactic and therapeutic trials using single or Ab cocktails; CD4bs Ab administration reduced viraemia in HIV-1 infected individuals. Alternatively, significant effort has been expended in generating vaccine candidates capable of inducing broadly neutralizing Ab against HIV env vulnerable sites. The current understanding of Ab affinity maturation in HIV-infected individuals indicates that successful immunization should induce a precise Ab lineage evolution toward a defined class of broadly neutralizing molecules that target the CD4bs or specific antigenic sites.

Complement Control Proteins

A number of viruses have been shown to bind to complement control proteins, also termed the regulators of complement activity (RCA). They protect the host from uncontrolled complement activation and lysis of intact self-cells. The RCA are soluble or membrane bound proteins composed of concatenated domains termed short consensus repeats (SCR) (Fig. 6), modules of about 60 amino acid residues and four invariant cysteines that form a compact barrel structure.

Epstein-Barr virus (EBV) attachment to B lymphocytes occurs by the interaction of the virus gp350/220 envelope glycoprotein with the cell-surface complement receptor 2 (CR2, CD21) or CR1 (CD35). CR2 possesses 16 extracellular SCR, the two most membrane-distal being the site of gp350/220 binding. The EBV receptor-binding region is targeted by neutralizing Abs, which indicates that blocking EBV-receptor interaction is a major neutralization mechanism. Nanoparticles that display the gp350-receptor recognition site elicit Abs that neutralize EBV, and are relevant vaccines candidates.

CD46 is a four-SCR protein expressed in all nucleated cells that acts as a cofactor in the proteolytic inactivation of C3b/C4b (Fig. 6(A)). It serves as the entry receptor of some MV genotypes, group B adenoviruses (Ad) and herpesvirus 6. The MV envelope hemagglutinin and the Ad fiber knob bind to a glycan-free surface formed by the most membrane-distal SCR1 and SCR2 (Fig. 6(A)), initiating virus cell entry. In MV, a unique concave surface with a socket accommodates CD46 and two other IgSF receptors, SLAM and Nectin-4, which facilitates virus dissemination among hosts and confers an extraordinary transmissibility to MV. CD46 virus and complement binding regions are not overlapping (Fig. 6(A)).

Decay-accelerating factor (DAF, CD55), an RCA-family protein with four SCR, is the receptor for a significant number of human EVs, including the group B coxsackieviruses (CVB) and many echoviruses (EchoV). The atomic structure of DAF shows a rod-shaped protein with four SCRs (**Fig. 6(B)**), separated from the membrane by a heavily glycosylated Ser/Thr-rich stalk. In contrast to many of the other examples presented here, where binding is to the membrane-distal domain of the receptor, the majority of the known DAF-binding EchoV interact with SCR3 (**Fig. 6(B)**), and with the second and/or fourth SCR domains. Virus and complement binding regions overlap (**Fig. 6(B)**). The interaction of DAF with EchoV occurs at a surface-exposed region or “puff” region, outside the canyon. Recently, the neonatal Fc receptor (FcRn) has been identified as an EchoV uncoating receptor that binds to the canyon.

Ectoenzymes

Ectoenzymes are membrane proteins with their catalytically active sites in the extracellular environment. They play diverse functions relevant to the regulation of homeostasis, and they are linked to numerous diseases and infections. Several ectoenzymes are entry receptors of Coronavirus (CoV), a large family of enveloped positive RNA viruses that infect a wide range of mammals and birds.

Aminopeptidase N (APN, CD13) was the first ectoenzyme to be related to CoV cell entry. It is a type II surface metalloprotease with a large ectodomain that forms dimers and contains a zinc ion at its active site (**Fig. 7(A)**). APN is termed a “moonlighting enzyme” because of its link to many cell functions. Another zinc metalloprotease, human angiotensin-converting enzyme 2 (ACE2), functions as the receptor for important human pathogens, the severe acute respiratory syndrome coronaviruses (SARS-CoVs). ACE2 is a type I membrane glycoprotein with an N-terminal extracellular domain built of two α -helical lobes (**Fig. 7(B)**); the catalytic site with a coordinated zinc ion is located between the lobes. More recently, a third ectoenzyme, dipeptidyl peptidase 4 (DPP4, CD26), was identified as the receptor of the middle east respiratory syndrome coronavirus (MERS-CoV). DPP4 is a type II membrane protein composed of two domains and forms homodimers. APN, ACE2 and DPP4 catalyze hydrolysis of short peptides and function in angiogenesis, cell adhesion and blood pressure regulation. Nonetheless, CoV selection of ectoenzymes as entry receptors is not determined by their enzymatic activity, which is not required for cell entry and infection.

CoV-ectoenzyme interactions

The major envelope spike (S) glycoprotein mediates receptor recognition and fusion in CoV. The trimeric S is composed of the S1 and S2 fragments and several recent structures have determined its domain architecture. The receptor-binding domains (RBD) that attach to ectoenzymes are at the most membrane distal pole of the S. Several crystal structures have described the molecular basis for CoV recognition of ectoenzymes.

The APN ectodomain is composed of four domains (DI-DIV), is heavily glycosylated and forms dimers through extensive DIV-DIV interactions (**Fig. 7(A)**). The CoV RBD interacts with a single APN monomer and preferentially contacts the membrane distal region of DIV. Human and animal CoV that belong to the alpha-CoV genus use extended loops that protrude at one edge of the RBD to attach to APN (**Fig. 7(A)**). Immune pressure has provoked marked differences on the receptor-binding loops generating different APN recognition among CoV.

The SARS- and MERS-CoV belong to the beta-CoV genus and are highly pathogenic in humans. The RBDs of these beta-CoVs contain an external subdomain specialized in receptor recognition, inserted in a central β -stranded core (**Fig. 7(B)** and **(C)**). In SARS-CoVs, the central concave subdomain surface cradles the ACE2 N-terminal α -helix, whereas the terminal side of the subdomain interacts with other ACE2 regions (**Fig. 7(B)**). Similarly, the MERS-CoV RBD engages the DPP4 molecule through the solvent-exposed side of its external subdomain (**Fig. 7(C)**). It contacts the edges of DPP4 β -propeller blades IV and V. N-linked glycosylations are engaged in CoV binding to DPP4 and APN and they are key determinants in CoV-receptor binding specificity. Subtle residue substitutions in the SARS and MERS receptor-binding subdomains increase their affinities for the human receptors, favor cross-species transmission and cause zoonosis.

Co-Receptors for Infection

Virus binding and entry is often a multistage process involving a cascade of interactions between the virus and host factors. The initial attachment is usually to the receptor, with subsequent interactions mediated by co-receptors. Commonly, specific virus interactions with the primary receptor and the co-receptor are necessary for virus penetration into the cell.

CBVs bind DAF at the cell surface, but infection also requires CAR, an IgSF protein with two extracellular domains. Differing from DAF, CAR engages the CBV canyon and triggers capsid conformational changes needed for entry. However, CAR is naturally located in tight junctions where it mediates homotypic cell adhesion, and is therefore not immediately accessible for virus attachment at the apical cell surface. Elegant studies have demonstrated that virus binding to DAF at the latter site results in Abl-kinase mediated signaling events which cause actin rearrangements that allow virus movement to the tight junctions where uncoating occurs. DAF binding also activates Fyn-kinase, which results in the phosphorylation of caveolin and subsequent virus entry in caveolin vesicles. CBVs therefore exploit the signaling capacity of their low-affinity primary DAF receptor to traffic to the high-affinity, uncoating CAR receptor and thereby cross the epithelial barrier.

Fig. 7 Ectoenzymes as coronavirus receptors. **A.** Dimeric APN-CoV structure. Ribbon drawing of the pig APN in complex with a porcine CoV RBD (PDB ID 4F5C). APN monomers (m) are shown with domains in orange (N-terminal DI), yellow (DII), red (DIII) and green (C-terminal DIV), as well as the N-terminal ends near the cell membrane. The bound RBDs are shown in blue and cyan, with the APN-binding surface in pink and two key residues in the domain tip in red. **B.** The SARS-CoV RBD bound to its ACE2 receptor. Ribbon drawing of the ACE2-RBD complex structure (PDB ID 2AJF). The RBD is shown with the core in yellow, the receptor-binding subdomain in dark red and the ACE2-binding surface in pink. Disulfide bonds as green cylinders. ACE2 is shown with the virus binding domain in green and the membrane-proximal lobe in orange. The three main ACE2 regions recognized by SARS-CoV are labeled in green. **C.** MERS-CoV binding to DPP4. Ribbon drawing of the dimeric DPP4-RBD complex structure (PDB ID 4KRO). The DPP4 monomers are shown with the virus binding, N-terminal-propeller domain in green and the C-terminal hydrolase domain in orange. The RBD core and the receptor-binding subdomain as described for SARS in panel B. Asn residues at glycosylation sites and the attached glycans are shown as sticks, with carbons in yellow in all the panels.

Fig. 8 The pathway of HIV-1 entry. Structure of the prefusion HIV-1 Env trimer ectodomain in the viral membrane, and the structures of the primary CD4 receptor (green) and the CCR5 co-receptor (red) in the target cell membrane. One gp120/gp41 heteromonomer in the trimer is shown in cyan and yellow, respectively, the other two gray. Binding of gp120 to the primary CD4 receptor (left) exposes the co-receptor-binding region and facilitates gp120 binding to CCR5 (right). Co-receptor engagement brings the trimer close to the cell membrane, initiates dissociation of gp120 and gp41 and the virus-cell membrane fusion. Inset: Conformational changes in gp120 and gp41 related to its dissociation and the insertion of the fusion peptide (magenta) into the cell membrane. Reproduced with permission from Cheng, B., 2019. Molecular mechanism of HIV-1 entry. Trends in Microbiology 27, 878–891.

Like poliovirus and rhinovirus, HIV binding to CD4 initiates conformational changes in the trimeric env that are a prerequisite for the subsequent fusion events (Fig. 8). However, unlike the two picornaviruses, interaction with the primary receptor exposes conserved residues that interact with a co-receptor, a necessary precursor to the fusion of viral and cellular membranes (Fig. 8). This requirement for a co-receptor explains why HIV can bind to human CD4 expressed on murine cells – which lack the co-receptor – without undergoing membrane fusion. The chemokine receptors CXCR4 or CCR5 function as HIV co-receptors; they belong to the seven-transmembrane-domain G-protein-coupled receptor superfamily. The importance of the chemokine co-receptor in HIV infection is supported by the observed genetic resistance to HIV of individuals with a deletion and frameshift within CCR5. Finally, the identification of chemokine receptors as critical co-receptors of HIV infection has also contributed to our understanding of virus tropism and evolution in vivo. CCR5-tropic strains of HIV are predominant for transmission and during the asymptomatic phase of virus infection. CCR5 is expressed at high levels in activated/memory cells and in gut-associated lymphoid tissue, the primary site of HIV replication. As infection progresses, CXCR4-tropic viruses evolve, able to exploit the wider tissue expression of the CXCR4 receptor.

Attachment Factors, Molecules That Facilitate Infection

Certain cell surface molecules cooperate in virus infection by promoting attachment to host cells and virus transfer to entry receptors on the cell surface or in endosomes. Attachment factors or receptors allow viruses to bind to the cell membrane, but additional interactions, for example with entry receptors, are required to mediate delivery of the virus or viral genome into the cytoplasm. Frequently, virus proteins, glycosylations or the virus lipidome recognize attachment factors – glycans or proteins – that facilitate cell infection.

For some viruses, the attachment factors that promote binding to permissive cells are quite well defined. Since they decorate cell surfaces, sulfated GAGs or HBGAs frequently serve as attachment factors for a range of viruses, including members of the flavivirus, picornavirus, papillomavirus, foamy virus, and calicivirus families. Sialylated glycans are also virus attachment factors that do not promote entry, for example in the case of Merkel cell PyV, while they function as entry receptors for many other viruses. The predominant display of specific glycan motifs on surfaces of different cells and tissues contributes to the host restriction and cell/tissue tropism of the virus.

HIV and Ebola virus (EBOV) envelope glycoproteins bear N-linked high mannose glycans that bind to the lectin dendritic cell-specific ICAM-grabbing non-integrin (DC-SIGN) (Fig. 9). These viruses employ DC-SIGN with different purposes. HIV-1 uses dendritic cells (DC) as a “Trojan horse” to move from mucosa to secondary lymphoid tissues. DC-SIGN bound viruses are stored in DC and presented to CD4⁺ cells, which mediates its trans-infection (Fig. 9(A)). Nonetheless, EBOV subverts DC-SIGN to penetrate into cell endosomes (Fig. 9(B)), where the EBOV envelope glycoprotein (GP) is processed and subsequently binds to its Niemann-Pick C1 (NPC1) entry receptor, which triggers membrane fusion and entry.

An alternative way of HIV-1 and EBOV attachment to DC through the virus lipidome has been identified. The HIV-1 envelope membrane contains gangliosides with a sialyllactose – sialic acid on galactose – moiety that binds to sialic-acid-binding

Fig. 9 Attachment factors in virus cell entry. **A.** Factors that mediate HIV-1 transinfection. HIV-1 uses membrane env and gangliosides bearing sialyllactose to bind to DC-SIGN and Siglec-1, respectively. Right: Siglec-1-bound virions in mature DC (mDC) are internalized; in secondary lymphoid tissues mDC present HIV-1 particles to CD4⁺ T cells and infection initiates. A similar process is described with DC-SIGN. **B.** Attachment factors facilitate the EBOV transfer to endosomes for membrane penetration. EBOV can use envelope GP or PtdSer to attach respectively to cell surface DC-SIGN or PtdSer-receptors such as TIM-1. Adhered particles are internalized by macropinocytosis and reach late endosomes, where proteases remove the GP mucin-like domain and the glycan cap and expose the receptor binding region. The particles can then bind to the NPC1 entry receptor, which mediates the fusion of viral and cell membranes, and the release of the nucleoprotein in the cell cytoplasm. Based on Izquierdo-Useros, N., Lorizate, M., McLaren, P.J., *et al.*, 2019. HIV-1 capture and transmission by dendritic cells: The role of viral glycolipids and the cellular receptor Siglec-1. *PLoS Pathogens* 10, e1004146.

immunoglobulin-like lectin-1 (Siglec-1) on the DC cell surface (Fig. 9(A)). The HIV-1 particles are captured by mature DC that express high Siglec-1 levels, and presented to CD4⁺ T cells in lymphoid tissues (Fig. 9(A), right). This trans-infection route is thought more relevant for HIV-1 transmission than engaging DC-SIGN because of the high amounts of Siglec-1 in different DC subsets. A similar retrovirus trans-infection route is also described in macrophages. Siglec-1 can function as an EBOV attachment receptor that facilitates virus penetration into DC endosomes.

Numerous studies with different viruses have demonstrated the relevance of virus membrane phosphatidylserine (PtdSer) in cell entry, which was first identified as a cofactor for HIV-1 infection of macrophages. PtdSer is a danger signal recognized by specific receptors that mediate the uptake of apoptotic cells. The implication of viral PtdSer in virus entry was first described as apoptotic mimicry with vaccinia virus, which penetrates into cells by macropinocytosis. More recent studies demonstrated that PtdSer receptors enhance entry and infection of alphavirus, baculovirus, flavivirus, filovirus and NewWorld arenavirus. It is proposed that EBOV can use PtdSer receptors such as TIM-1 to gain access to its entry receptor in late endosomes (Fig. 9(B)). Nonetheless, the enhancing activity of PtdSer-receptors on virus entry is mostly described *in vitro*, and the relevance of these receptors on virus infection is still under discussion.

Evolution of Virus-Receptor Interactions and Viral Tropism

Due to the possession of error-prone replication strategies, many viruses exhibit an exquisite ability to adapt to the environment in which they are grown. Virus-receptor interactions are constantly subject to changes because of evolutionary pressure to increase the virus infection efficiency and to escape from immune surveillance. Numerous modifications on the receptor-binding regions lead to the emergence of a new pathogen with altered infectivity, tissue tropism, or host range.

Using a conserved binding site, many human polyomaviruses bind to N-acetyl neuraminic acid, a carbohydrate that is prominently present on the surface of human cells. In contrast, the non-human polyomavirus simian virus 40 (SV40) binds to N-glycosyl neuraminic acid, a modified sugar that is present in monkeys (SV40 host) but that is absent in humans. The two

neuraminic acid variants differ only by a single hydroxyl group, and the sialic acid binding pocket of SV40 differs from that of closely related human polyomaviruses at only very few positions that enable SV40 to accommodate the additional hydroxyl group present in the glycolyl group. Thus, subtle modifications in a binding pocket can enable a virus to change its host range.

Adenoviruses have evolved to recognize a range of different protein and glycan receptors (CAR, CD46, the GD1a glycan and desmoglein-2) using the same protein, the fiber knob. Here, more extensive amino acid substitutions lead to changes in surface loop structure that endow a given knob with the ability to interact specifically with one of these receptors. Adenoviruses that infect the eye and cause Epidemic Keratoconjunctivitis, for example, use the GD1a glycan as their receptor, and since this glycan is heavily expressed on human corneal cells the ability of the virus to bind GD1a is linked to tissue tropism.

In CoVs, the evolution in receptor recognition can lead to receptor specificity switches as well as to inter-species transmission and zoonosis. The APN recognition mode in the human CoV-229E diverged from related animal CoV of the alpha genus, whereas the human NL63-CoV switched to the recognition of ACE2. These divergences among related CoVs are due to immune pressure over the receptor binding region, which causes conformational changes in the receptor-interacting motifs to escape from Ab neutralization. The emergence of the SARS- and MERS-CoVs, which are responsible for severe respiratory syndromes, generated greater interest on CoV evolution. These viruses originated in bats, their natural reservoir, adapted to intermediate hosts – civets for SARS and dromedary camels for MERS – from which they transmitted to humans. The efficient transfer of SARS- and MERS-CoVs from bats to humans is due to increased affinity for their human orthologue receptors. These CoVs contain large receptor binding subdomains (Fig. 7(B) and (C)), which accommodate subtle residue substitutions that increase their affinity for the human receptor proteins and facilitate its transmission to man, where they cause severe diseases. Adaptive mutation in the CoV S also facilitates their spread among the human population.

EBOV is transmitted from bats to primates and generates recurrent outbreaks in Central Africa. It is thought that efficient EBOV transmission to humans is related to the receptor binding properties of the EBOV GP. Whereas most EBOV in Central Africa affected a limited number of individuals, the Ebola epidemic that began in West Africa at the end of 2013 spread rapidly and reached an unprecedented scale. It was caused by a variant named Makona, which evolved during the epidemic toward an enhanced primate cell infectivity. Some of the acquired residue substitutions mapped at the Makona GP receptor-binding region, and it is hypothesized that they facilitate the interaction with cell surface receptors. Evolution of the EBOV-receptor binding features in the human population can thus lead to an increased human-to-human transmission and to epidemics.

Summary

Virus receptors are key components of the early events involved in cell infection by mediating attachment as well as conformational changes in the virus that lead to cell entry. In addition, they provide mechanisms for internalization in which the virus may subvert a natural receptor cycling process. Furthermore, the identification of virus receptors contributes significantly to our understanding of host, tissue, and cell tropism, and helps explain aspects of virus pathogenesis. Insights into virus-receptor interactions can inform the rational design of vaccines that elicit virus immune neutralization.

The selected bibliography illustrates relevant and recent research on different aspect of viruses and their receptors.

Nomenclature

dsDNA Double-stranded DNA
dsRNA Double-stranded RNA

ssDNA Single-stranded DNA
ssRNA Single-stranded RNA

Glossary

Adsorption Initial interaction between a virus particle and a cellular receptor molecule.

Archaeal virus A virus that infects archaea.

Bacterial virus, bacteriophage or phage A virus that infects bacteria.

Capsid The protective protein coat of a virus particle.

Capsule External polysaccharide layer outside the bacterial cell envelope.

Cell envelope Plasma membrane and cellular structures located outside the plasma membrane.

Cell wall Cellular structures located outside the plasma membrane.

Lipopolysaccharide A unique glycolipid of the outer membrane of gram-negative bacteria.

Peptidoglycan A polymer consisting of long glycan chains cross-linked via peptide bridges and forming a

homogenous layer outside the plasma membrane of eubacteria.

Receptor A specific molecule or molecular assembly exposed on the surface of a cell to which a virus entering the cell attaches.

Receptor-binding protein A virion protein responsible for the interaction of a virion with a specific cellular receptor molecule.

Surface layer (s-layer) A cell surface layer composed of proteins or glycoproteins commonly found from archaea and sometimes also from bacteria.

Vertex Five-fold symmetry position of the icosahedra; one icosahedral particle has 12 five-fold symmetry positions.

Viral envelope An outer lipid-protein bilayer of a virus.

Virion A virus particle, the extracellular form of a virus.

Introduction

Viruses are intracellular parasites that are dependent on the metabolic apparatus of the cell. Unlike other parasitic self-replicating systems, such as plasmids and viroids, viruses possess an extracellular phase that allows spread from one infected cell or organism to another. Consequently viruses have to have means to infect new host cells. The entry into a suitable host cell is a key event for the viral reproduction and survival. These processes are understood in depth for several bacterial viruses. Information on archaeal virus entry is also emerging and discussed here alongside bacterial virus entry strategies.

Host Cell Barriers

The nature of the host cell envelope has a great influence on the viral entry strategy. Most bacteria and archaea have a multilayered cell envelope forming a complex physical barrier that the entering virus has to pass. Gram-positive bacteria have a single internal lipid bilayer and a thick cell wall made of peptidoglycan (also known as murein) while Gram-negative bacterial cells are covered by an internal membrane, a thin layer of peptidoglycan, and an outer membrane. The outer membrane is an asymmetric bilayer containing lipopolysaccharides in its outer leaflet. In addition, bacterial cells may secrete polysaccharides (e.g., alginate, hyaluronic acid, or polysialic acids) that make a protective extracellular capsule on the surface of the cell envelope. The extracellular capsule masks the cell surface receptors and efficiently restricts phage access. Archaeal cell surface structures are more diverse than those described for bacteria. The cell wall of the best-characterized archaea is composed of a proteinaceous surface (S-) layer made of pseudocrystalline protein or glycoprotein arrays. Archaeal cell wall may also contain peptidoglycan-like polysaccharide, called pseudomurein, or other types of polymers (e.g., methanochondroitin). In addition, wall-less forms of bacteria and archaea exist.

The relatively strong and inert cell envelope of bacteria and archaea efficiently restricts the passage of macromolecules. Moreover, bacterial and archaeal cells do not employ endocytic-like uptake systems, which are commonly exploited by eukaryotic viruses. These host features strongly influence the strategies utilized by bacterial and archaeal viruses to gain access into the host cytoplasm. In fact, the capsids of most bacteriophages are not internalized into the host cell, and only the viral genome, often with some protein factors, is delivered across the host envelope to the cytoplasm. In this way, small opening in the bacterial or archaeal cell envelope is sufficient for successful virus entry.

Virion as a Genome Delivery Device

Virions represent an extracellular form of the virus. It is a vehicle, which allows the virus to resist the harsh environment outside the cell. In addition to its protective nature, the main task of the virion is to recognize the host and to deliver the viral genome with necessary accessory factors to the new host cell. The mechanism of the genome delivery is typically reflected in the structure of the virion (see below). Thus, viruses sharing similar virion morphology often have similar entry pathways.

Furthermore, the nature of the viral genome influences the mechanisms of virus entry. Viruses that have genomes, which cannot be expressed using the enzymatic apparatuses of the host, need to also bring viral polymerases into the host cell. This applies to those bacterial viruses which have dsRNA genomes. Regardless of the type of the genome, many viruses deliver some accessory protein factors inside the host. These are required in the early stage of the infection, prior to the viral genome expression, either to complete the entry process or for successful genome replication and expression.

Host Recognition and Adsorption

Adsorption of viruses to their host cells often involves three steps: (1) initial virus contact with the cell, (2) reversible virus adsorption, and (3) subsequent irreversible adsorption. The first step, which is non-specific, brings the virus close to the cell and occurs through random events such as Brownian motion or diffusion. By reversible adsorption, the virus binds to the outermost cell surface components (i.e., the primary receptor) and then can detach and bind again, thereby searching for a specific cellular receptor (the secondary receptor). Irreversible adsorption takes place, when the virus encounters and binds to a specific cellular receptor.

The recognition and adsorption occurs via receptor-binding proteins located on the surface of the virion. These proteins recognize specific receptor molecules exposed on a susceptible cell. The receptor-binding proteins are often localized in the vertices of the icosahedral virions, the tips of the helical virions, or on the surface of the viral envelope. In tailed bacteriophages the initial recognition (reversible adsorption) is carried out by the fibers that are connected to the tail (Fig. 1(a)). The specific recognition of the cellular receptor leads to irreversible structural rearrangements in the virion components; the viral receptor-binding complexes overcome an energy barrier and fold into a minimal energy state. These conformational changes lead to more tight (irreversible) attachment and eventually trigger the entry process. The rigid structure of the virion or some part of it (e.g., one vertex of an icosahedral virion) is destabilized so that the genome delivery can be accomplished.

In terms of cellular receptors, many bacteriophages, including icosahedral ssRNA (e.g., MS2, Q β), filamentous ssDNA (e.g., Ff), and enveloped dsRNA (ϕ 6) phages, utilize a bacterial pilus as their primary receptor. Similarly, attachment to pilus-like filamentous structures has been documented for rod-shaped rudivirus (SIRV2) and enveloped filamentous lipothrixvirus (AFV1) infecting archaeal hosts. Binding to the pilus enables efficient capture of the virion at a distance from the cell surface, and the retraction of the pilus translocates the bound viruses to the host envelope (Fig. 1(b)). This allows virions to get access to the cell surface regardless of the polysaccharide capsule, which could restrict the easy access to the cell surface. Some bacteriophages (e.g., K1–5, K5, K1E), however, may also use the polysaccharide capsule as the initial site of recognition and binding, and by enzymatic degradation of the capsule get access to the cell surface (see below).

Other receptor sites for bacteriophages are cell surface lipopolysaccharides, various cell envelope and flagellar proteins, as well as cell wall carbohydrates. The tailed phages infecting Gram-positive bacteria typically attach to the cell wall teichoic acids, while those infecting Gram-negative bacteria use either the lipopolysaccharide moieties (e.g., T2, T4, T7) or envelope proteins, such as porins and transporters (e.g., PP01, T1, T5, λ) as their receptors. Among archaeal viruses, the acidianus two-tailed virus also utilizes archaeal cell surface transporter protein as its receptor.

Viral Enzymes in Capsule and Cell Wall Penetration

The virions of many bacteriophages contain enzymes, which degrade cell wall polymers and thereby facilitate virion access to the plasma membrane. These depolymerizing enzymes are encoded by the viral genome and, after expression in the cell, incorporated into the virions during their assembly. A number of different types of depolymerases have been identified in the genomes of bacteriophages, including endosialidases, hyaluronidases, levanases, xylosidases, dextranases, peptidases and pectin lyases. Beside their importance in the viral replication cycle, bacterial cell wall degrading enzymes have great biotechnological and biomedical potential.

The tail spikes of tailed phages that use exopolysaccharides for their attachment, have exopolysaccharide degrading activity which assist in the penetration of the bacterial capsule. Depending on the phage and the chemical composition of the host extracellular polysaccharide these enzymes are typically either endosialidases (e.g., *Escherichia coli* phages K1–5 and K1E) or hyaluronidase (e.g., *Streptococcus pyogenes* phage SF370.1). Other types of phage encoded exopolysaccharide depolymerases have been also described. Due to the sequential action of the polysaccharide depolymerases, the phage virion can drill through the capsule layer and reach its secondary receptors at the cell envelope.

O-polysaccharide specific enzymes are found in the virions binding to the O-polysaccharide moieties of the outer membrane lipopolysaccharides found in Gram-negative bacteria. Endorhamnosidase present, for example, in the tailed *Salmonella* phage P22 and O-antigen deacetylase present in *Escherichia* phage G7C are able to modify the O-polysaccharide chain length or its composition, respectively. The enzymatic activity of the O-polysaccharide specific enzymes apparently facilitates the irreversible binding to the host outer membrane and primes the virion for genome delivery.

Fig. 1 Schematic presentation of the main entry strategies utilized by bacterial viruses. OM, outer membrane; PG, peptidoglycan; PM, plasma membrane. (a) Genome delivery through an icosahedral vertex; given example is a phage with long-contractile tail from the family *Myoviridae* (e.g., T4). Primary interaction between the phage and the host cell is mediated by the long tail fibers (black) and short tail fibers (brown). Contraction of the tail sheath (orange) facilitates the penetration of the cell envelope. The viral genome (purple) is released from the head of the phage virion through the tail tube (dark blue) into the host cytosol. The protein capsid remains outside the cell. (b) Dissociation of filamentous phage capsid at the cell envelope. The receptor binding protein (orange) located at the tip of the helical virion interacts with the bacterial pilus (gray). Pilus retraction brings the virion on the cell surface enabling interaction with the co-receptor molecule TolQRA complex (dark gray). The viral genome (black) is released into the host cytosol as the virion capsid proteins (blue) are inserted into the plasma membrane (PM). (c) Penetration of the nucleoprotein complex of an enveloped dsRNA virion. The viral spike proteins (orange) on the virion surface mediate the interaction between the host and the virion. Fusion between the host outer membrane (OM, green) and phage envelope (blue) takes place leading to the mixing of host and viral lipids. The nucleoprotein assembly (nucleocapsid; light orange) released into the bacterial periplasm penetrates the peptidoglycan network with the aid of a lytic enzyme (black) located on the nucleocapsid surface. Subsequently, the host plasma membrane is penetrated via an endocytic-like process.

In addition to the above discussed depolymerases, the virions of many bacteriophages contain peptidoglycan-hydrolyzing or modifying enzymes. These are specialized proteins that locally and temporarily disrupt the peptidoglycan network, thus allowing the penetration of the cell wall. Similarly to exopolysaccharides and lipopolysaccharides degrading enzymes, the peptidoglycan-hydrolyzing enzymes of tailed bacterial viruses are often associated with the tail structures or, in the case of some short-tailed phages (e.g., T7), with internal head proteins that are ejected at the beginning of the infection cycle. Icosahedral dsDNA phages with an internal membrane and no tail (e.g., PRD1, Bam35) as well as the enveloped dsRNA phage $\phi 6$ also possess peptidoglycan-hydrolyzing enzymes in their virions (see below). The most common cell-wall-degrading enzymes found in bacteriophage virions are lysozymes (N-acetylmuramidases) and lytic transglycosylases.

Genes encoding cell wall degrading enzymes, pseudomurein endoisopeptidases, have also been identified in a few tailed archaeal viruses of methanogens (e.g., ψ M2 and provirus ψ M100). However, it is not clear whether these enzymes are structural proteins of the virion, and thus could participate the cell wall penetration during virus entry, or if they contribute to the host cell lysis and release of progeny virions in the end of the infection cycle. Furthermore, most archaea do not have pseudomurein cell wall but rather have an S-layer, which displays a substantial diversity between different species. No S-layer specific proteases, which could assist in S-layer penetration have been currently identified in archaeal viruses.

Despite the wide distribution and variety of phage encoded enzymes, not all viruses require specialized enzymes for the penetration of the host cell wall during entry. Several phages are known to rely on preexisting channels within the host envelope. This applies to icosahedral and filamentous ssDNA bacteriophages (e.g., ϕ X174 and M13, respectively) as well as icosahedral ssRNA bacteriophages (e.g., MS2). For example, infection of filamentous ssDNA phages absolutely depends on a protein complex assembled in the bacterial plasma membrane spanning the peptidoglycan layer (Fig. 1(b)).

Genome Delivery Mechanisms of Phages

In general, entry strategies of bacterial viruses fall into three main categories: (1) genome delivery through an icosahedral vertex, (2) virion dissociation at the cell envelope, and (3) virion penetration via membrane fusion and an endocytic-like event (Fig. 1). Tailed dsDNA phages (e.g., T4, T5, T7), dsDNA phages with an internal membrane (tequiviruses), as well as icosahedral ssDNA and ssRNA phages deliver their genome through a genome delivery apparatus located at one of the capsid vertices (Fig. 1(a)). Capsids of filamentous phages (e.g., M13) and membrane-containing icosahedral phage PM2 disassemble completely at the cell envelope (Fig. 1(b)), whereas the enveloped dsRNA bacterial viruses utilize a unique membrane fusion-type uncoating at the outer membrane and virus subparticle internalization through the plasma membrane (Fig. 1(c)).

Icosahedral Tailed dsDNA Bacterial Viruses

Tailed dsDNA bacteriophages represent the most abundant morphotype among bacterial viruses. The tailed viruses are also common among known isolates of archaeal viruses. The virion of such viruses is comprised of an icosahedral capsid (head) enclosing highly condensed viral DNA, and a helical tail attached to a unique vertex of the capsid. The tail is a multiprotein tubular apparatus responsible for the host cell recognition, attachment and cell envelope penetration. Despite the numerous isolates of tailed viruses, they all possess one of the following three types of tails: long contractile (family *Myoviridae*, e.g., T4; *Ackermannviridae*; *Herelleviridae*), long noncontractile (family *Siphoviridae*, e.g., T5), or short noncontractile tail (family *Podoviridae*, e.g., T7 and ϕ 29). The type of tail influences the genome delivery mechanism utilized by the tailed viruses.

Bacteriophage T4 infecting Gram-negative bacteria is a classic example of a tailed phage. The contractile T4 tail is composed of four major parts: the terminator, the rigid central tube, the contractile sheath around the tail tube, and the base plate complex. The central tube is made of many copies of the tail tube protein, which are stacked around an extended tape measure protein present in few copies. A contractile sheath built of many copies of the tail sheath protein surrounds the tail tube. The proximal end of the tail ends with the tail tube terminator and the sheath terminator, and attaches to the head via neck and portal structures. The portal is a specialized vertex, through which the viral DNA is packaged into the head. The distal end of the tail tube is attached to the base plate, a complex structure decorated with long and short tail fibers terminating the tail (Fig. 1(a)). The long tail fibers act as sensors to detect the host bacterium and serve for the primary attachment. The short tail fibers, initially folded beneath the base plate, unfold and bind irreversibly to the host bacterium. Interaction between the tail fibers and their surface receptors leads to conformational changes in the base plate (base plate transition from dome-shaped to star-shaped) which triggers contraction of the tail sheath to about half of its original length (Fig. 1(a)). Due to the contraction of the tail sheath and the irreversible attachment of the tail fibers to the cell surface, the tail tube moves towards the cell envelope and penetrates it (Fig. 1(a)). The peptidoglycan-hydrolyzing enzyme associated with the tip of the tail tube facilitates the penetration of the peptidoglycan layer. Eventually the tail tip reaches the plasma membrane and fuses with it. The force required for penetration of the tail tube through the cell envelope is associated with the contraction of the tail sheath. Some viral proteins enter the cell along with the phage DNA in order to protect it from host exonuclease activities and are implicated in the early stages of phage genome transcription.

The long noncontractile tail of siphoviruses such as λ , T5, HK97 and SPP1, is composed of trimers (e.g., T5) or hexamers (e.g., SPP1) of a tail tube protein polymerized around few copies of the tape measure protein. The tape measure proteins in their elongated conformation span the whole tail tube and the C-termini of these proteins together with several other proteins form the tail tip complex at the distal end of the tube. The receptor binding protein of T5 is part of the tail tip. The relatively flexible tails of

siphoviruses may also possess the long tail fibers serving for reversible attachment to the host cell as exemplified by T5 and λ phages. In contrast to myoviruses, tails of siphoviruses do not possess a contractile sheath and therefore do not contract during DNA transfer from the virion to the cell. The tail tube protein of T5 does not undergo conformational changes upon receptor binding and thereby plays no role in the signal transmission from the tail tip to the head. The conformational changes mostly concern the tail tip and therefore it is suggested that the tape measure protein is involved in the signal transmission from the distal end of the tail to the head upon receptor binding. The tape measure proteins are released from the tail tube into the periplasm of Gram-negative host bacterium after irreversible binding to the receptor (FhuA in the case of T5 or LamB in the case of HK97). The host cell proteins such as periplasmic chaperones and inner membrane proteins are involved in the later stages of the siphovirus genome translocation to the cell cytoplasm. The periplasmic chaperones (FkpA in HK97 infection) might aid the tape measure proteins in adopting a conduit conformation suitable for DNA transfer through the cell envelope. The inner membrane proteins of the host cell (PtsG in HK97 infection) possibly facilitate the phage entry by anchoring the viral protein conduit to the inner membrane or by providing a pore in the inner membrane for DNA transfer.

Podoviruses possess short noncontractile tails and, compared to other tailed viruses, exhibit simplest tail morphology. The tails of podoviruses, like P22, ϕ 29 and T7, are formed by a nozzle also known as central knob, which is decorated with trimeric appendages called fibers or spikes. The tail is attached to the unique vertex of the head via adapter proteins forming a dodecameric ring. The podovirus tails are usually too short to span the host cell envelope and therefore additional proteins are needed for DNA translocation across the cell envelope. In the intact virion these proteins either form the internal core structure of the head (like in the case of T7 and P22) or are located in the tail (for example the terminal loops of the ϕ 29 tail knob). Bacteriophage T7 infecting Gram-negative bacteria uses tail fibers to recognize the lipopolysaccharide moieties of the host rough strains (the lipopolysaccharide molecules of such strains lack the O-antigen). Irreversible adsorption of T7 tail to the outer membrane leads to the ejection of several proteins from the virion to the cell's periplasm. After ejection, these proteins associate with the inner and outer membranes of bacterial envelope creating a channel for DNA translocation spanning the periplasm. This process has been visualized by cryo-electron tomography showing conduit in the bacterial periplasm made of viral core proteins, which were ejected from the head upon irreversible T7 adsorption. Moreover, one of the proteins ejected from the virion possess the transglycosylase activity, which helps to overcome the peptidoglycan layer of the cell envelope. After conduit is assembled, the transfer of T7 DNA from the virion to the cytoplasm occurs in a stepwise manner. First, a small portion of the viral DNA (approximately 1 kb out of 40 kb) exits from the virion spontaneously. Subsequently, the rest of the genome is internalized enzymatically via transcription by host RNA polymerase and then by viral RNA polymerase. The stepwise mode of viral genome translocation provides effective means for gene regulation, as genes that first enter the cell are expressed first; genes encoding structural proteins are required late in the infection and are expressed late because they are not present in the cell at early stages of infection.

Podoviruses infecting Gram-positive bacteria such as ϕ 29, have to penetrate the thick layer of peptidoglycan constituting the cell wall of these bacteria. The ϕ 29 entry initiates when appendages of the virion attach to the cell wall teichoic acids protruding on the cell surface. The enzymatic activity present in the appendages digests the teichoic acid chains thereby pulling the virion closer to the cell wall. When the ϕ 29 tail touches the peptidoglycan layer, the enzymatic activity present in the tail tip hydrolyzes the peptidoglycan thus clearing the path for the virion towards the cytoplasmic membrane. Upon interaction with the membrane, the tail tip undergoes structural changes and transmembrane pore is formed through which viral DNA is delivered to the cytoplasm. The hydrophobic loops present at the end of the tail knob of ϕ 29 were suggested to form a transmembrane pore for DNA translocation.

The archaeal tailed viruses share similar morphology with the bacterial myoviruses, siphoviruses and podoviruses. It is expected that they use the tail for genome delivery and that their entry pathways are similar to the above described tailed bacterial viruses.

Icosahedral DNA Viruses With an Internal Membrane

Several icosahedral bacterial and archaeal viruses have lipid-protein membrane residing beneath the protein capsid. Despite of the structural similarity, the genome of such viruses can be either linear or circular dsDNA (PRD1 and PM2, respectively), or circular ssDNA (FLiP). The role of the internal membrane in the entry process is best characterized for bacteriophage PRD1, the type member of the *Tectiviridae* family.

Bacteriophage PRD1 infects Gram-negative hosts which harbor a multiple drug resistance conjugative plasmid. This plasmid encodes the receptor complex that is recognized by the spikes located at the icosahedral vertices of the PRD1 virions. Specific interactions between the phage and the host induce dissociation of the spike complex from one of the capsid vertices and subsequent formation of a pore in the viral capsid. The internal membrane is transformed into a proteo-lipidic tube, which protrudes from one of the capsid vertices and provides a conduct for passage of the viral genome through the outer layers of the host cell, analogous to the tails of the dsDNA bacteriophages discussed above. Lytic transglycosylase associated with the PRD1 membrane assist the tube in the peptidoglycan penetration. Once the tip of the tube has reached the host cytoplasm it unplugs resulting in the translocation of the viral genome via the tube to the host interior. The rigid protein capsid stays intact outside the cell. The members of *Tectiviridae* that infect gram-positive bacteria (e.g., Bam35) attach directly to the host cell peptidoglycan structure. The internal membrane of these viruses can also transform into a tubular structure suggesting similar mechanism for DNA entry into the host cell.

Bacteriophage PM2 (*Corticoviridae*) infects gram-negative marine bacteria from genus *Pseudoalteromonas*. Although PM2 share a similar structural organization with PRD1 and other tectiviruses, it uses a distinct entry pathway. The capsid of PM2 dissociates on the host cell surface releasing the internal lipid core enclosing the viral DNA. A current model suggests that the viral membrane then fuses

with the bacterial outer membrane delivering the highly supercoiled dsDNA genome into the periplasm, from where it travels to the host cytosol. Whether the recently isolated membrane containing ssDNA phage FLiP (family *Finnlakeviridae*), or the archaeal dsDNA viruses having integral membrane layer in their virions (e.g., SH1, HCIV-1, and HHIV-2 of the family *Sphaerolipoviridae*) have entry pathways similar to PRD1 or PM2, or use alternatively some yet unknown entry mechanisms, remains to be discovered.

Pleomorphic DNA Viruses

The quasi-spherical virions of pleomorphic dsDNA bacterial viruses (*Plasmaviridae*) are nucleoprotein complexes within a lipid-protein membrane. The only classified member of the family *Plasmaviridae* is Acholeplasma phage L2. Acholeplasma are wall-less bacteria; thus, the phage adsorbs directly on the plasma membrane. It is assumed that adsorption leads to fusion of viral and host cell membranes resulting in entry of the nucleoprotein complexes into the cell. Similar entry strategy has also been proposed for haloarchaeal pleomorphic ssDNA and dsDNA viruses of the family *Pleolipoviridae* including Halorubrum pleomorphic virus 2 and 6 (HRPV-2 and HRPV-6). The virion of these viruses is decorated by a monomeric envelope surface protein which can mediate the fusion between the viral membrane and the host cytoplasmic membrane.

Icosahedral ssDNA Bacterial Viruses (With no Membrane)

The icosahedral ssDNA bacterial viruses of the family *Microviridae* infect Gram-negative bacteria (e.g., Escherichia phages ϕ X174, G4, and α 3) or obligate intracellular parasites lacking a cell wall, like chlamydia (e.g., Chp2) and spiroplasma (SpV4).

Icosahedral ssDNA bacterial viruses infecting Gram-negative bacteria contain large pentameric spike complexes (made of protein G in ϕ X174) at the vertices of the virion. These spikes are responsible for the initial binding of the phage to the host cell envelope. Binding to the lipopolysaccharide is mediated by one of the twelve spikes and it results in the dissociation of the interacting spike. This triggers conformational changes in the exposed major capsid protein resulting in its attachment to the lipopolysaccharide, and opens a gate in the capsid vertex bound to the cell surface. Additional changes in the pilot protein (H) and the ssDNA genome within the capsid further prime the virion for genome delivery. The pilot protein oligomerizes into super-helical coiled-coil structure which forms a tube-like conduit for genome translocation through the cell envelope. Both the genome and the pilot protein are eventually internalized into the host cell cytoplasm while the viral capsid lacking DNA and one of 12 minor spike proteins remains outside the cell. Entry pathways of microviruses infecting wall-less parasitic bacteria is less well studied and therefore not discussed here.

Filamentous DNA Viruses

Most of the filamentous non-enveloped ssDNA viruses from family *Inoviridae* identified to date infect Gram-negative bacteria, like Escherichia phages M13, F1, and Fd (known as Ff phages), or wall-less bacteria like Acholeplasma virus L51 and Spiroplasma virus C74. The Propionibacterium virus B5 is the only classified filamentous ssDNA phage infecting Gram-positive bacteria. Filamentous viruses infecting archaea usually possess dsDNA genomes and are more diverse in their morphology. Filamentous archaeal viruses that belong to families *Lipotrixviridae* and *Tristromaviridae* are enveloped and those that belong to *Rudiviridae* and *Clavaviridae* are non-enveloped viruses. The Ff phages infecting Gram-negative bacteria are the best studied filamentous viruses. The virion of Ff phages is composed of thousand copies of major coat protein pVIII helically arranged around the circular ssDNA. Both ends of the virion are terminated by two different minor coat proteins, pVII and pIX at one end, and pIII and pVI at the other end. The receptor-binding protein of Ff phages, pIII, is located at one end of the phage filament. The primary binding site of these viruses is bacterial pilus, a long thin proteinaceous structure on the surface of bacteria. The Ff phages adsorb to the tip of F pilus (conjugative type IV secretion pilus), other filamentous phages may also adsorb to the type IV pili (T4P). Binding of pIII protein to the tip of F pilus induces conformational changes in the pIII uncovering the receptor binding domain. Both type of pili can retract thereby bringing attached phages close to the receptor located in the periplasm of bacterial cells. How exactly filamentous phages cross the outer membrane is not known. Possibly they can use pilus structures spanning the outer membrane to reach the periplasm. To traverse the periplasmic space, most filamentous phages utilize a trans-envelope protein complex, Tol system. The exposed receptor binding domain in pIII of Ff phages interacts with the periplasmic part of TolA subunit, which is anchored to the inner membrane via its transmembrane helix. The pIII interaction with TolA leads to the insertion of pIII and the major coat protein pVIII subunits into the bacterial inner membrane resulting in stepwise dissociation of the filamentous capsid and concomitant uncoating of the phage genome at the cytoplasmic membrane. Eventually, this uncoating process results in the delivery of the viral ssDNA genome into the cytoplasm of the host cell (Fig. 1(b)). The TolQ and TolR subunits making a complex with TolA in the inner membrane can facilitate this process, though their exact role is not clear. The entry of filamentous viruses infecting Gram-positive bacteria and archaea has not been elucidated to date.

Icosahedral Enveloped dsRNA Bacterial Viruses

The dsRNA bacteriophages of the family *Cystoviridae* have a unique entry mechanism among bacteriophages. Similarly to eukaryotic dsRNA viruses, cystoviruses deliver their genome into the host cytoplasm within a large protein capsid, which protects the enclosed dsRNA genome throughout the infection cycle.

The enveloped virion of dsRNA bacteriophages contains three structural layers that sequentially assist in the penetration of the host outer membrane, the peptidoglycan layer, and the plasma membrane. The spikes protruding from the virion surface are involved in the receptor recognition and binding (**Fig. 1(c)**). The dsRNA bacteriophages adsorb either to a bacterial pilus (e.g., *Pseudomonas* phage $\phi 6$), which then retracts, or to lipopolysaccharide on the surface of the gram-negative host bacterium (e.g., *Pseudomonas* phage $\phi 13$). After phage adsorption at the outer membrane, the viral envelope fuses with the host membrane, thus uncoating the virion and placing the resulting viral nucleoprotein complex (or nucleocapsid) into the periplasm (**Fig. 1(c)**). The fusion between the viral envelope and bacterial outer membrane is driven by the transmembrane proteins of the viral envelope, whose fusogenic properties are activated after virus adsorption. The lytic enzyme of the virus located between the envelope and nucleocapsid locally digests the host cell-wall peptidoglycan, thereby allowing the nucleocapsid to reach the plasma membrane (**Fig. 1(c)**). The nucleocapsid then binds to the plasma membrane lipids inducing the formation of plasma membrane invagination. Eventually, the nucleocapsid penetrates the plasma membrane via an endocytic-like route. This involves the formation of the plasma membrane curvature at the contact site resulting in an intracellular vesicle, which then pinches off from the plasma membrane (**Fig. 1(c)**). This process is dependent on the energized host plasma membrane. The transcriptionally active viral particle is released from the vesicle into the host cytosol.

Icosahedral ssRNA Bacterial Viruses

Icosahedral ssRNA viruses that infect bacteria belong to a single family *Leviviridae*. Thus far there are no known RNA viruses infecting archaea. The best studied leviviruses are *Escherichia* phage MS2 and Q β . The virion of MS2 contains ssRNA genome enclosed by 89 coat protein dimers and a single copy of maturation protein, which replaces one of the coat protein dimers in the capsid. The maturation protein strongly interacts with the 3' end of the viral RNA and is also responsible for the attachment to the bacterial F pilus. Similarly to the other viruses utilizing pili, retraction of a pilus brings the virion to the surface of the bacterial cell. Binding to the pilus does not trigger the genome release which suggests that the energy required to pull the genome out of the capsid comes from the pilus dynamics, rather than the attachment. Eventually, the maturation protein dissociates from the capsid and is delivered to the cell cytoplasm together with the tightly bound RNA. The empty capsid is left outside the cell. Bacteriophages with ssRNA genomes do not possess peptidoglycan-hydrolyzing enzymes present in many other bacterial viruses to facilitate the peptidoglycan penetration during the entry process. Instead, ssRNA phages rely on the host cell pilus to reach the cytoplasm.

Summary

Many bacterial viruses encode different types of cell wall degrading or modifying enzymes that are incorporated into the virion. These enzymes help viruses to get access to the host plasma membrane during entry. Typically, the viral genome is delivered into the host via a specific tubular structure which is part of the virion or is formed upon virion binding to the host cell surface. Regardless of the origin and composition of the tube, it is used to deliver the genome from the icosahedral viral capsid to the host cytoplasm, while most of the other parts of the virion remain outside the cell. Alternatively, the virion dissociates at the cell envelope resulting in the uncoating of the genome and its delivery into the host cell. In rare cases, the genome enters into the host cell within an icosahedral viral capsid.

Preamble

Non-enveloped viruses represent a diverse range of infectious agents found across the phyla. They include well known viruses, largely as a result of the pathology they cause, such as poliovirus, rotavirus and the papilloma viruses, to silent yet widely distributed viruses such as transfusion transmitted (TT) virus. Some non-enveloped viruses are classified as emerging viruses such as Deformed Wing Virus of the honeybee, enterovirus D68 in man and circovirus infection in mammals and birds. Indeed, any list of non-enveloped viruses of concern would date rapidly as more and more members are added. The diversity of non-enveloped viruses is mirrored by the pathology they cause which in turn is related to the type and range of tissues infected. Their mode of transmission, airborne, blood borne or by direct contact is also dictated in many cases by their sites of replication. Central to this diversity and its consequences is the target cell for virus entry and the mechanisms used by the virus to gain access into it. With the exception of plant viruses, which require physical breakage of the hard cell wall to enter, the outline process is the same for the majority of viruses, non-enveloped included; locate to the cell surface using a specific or general receptor, enter the cell in an invaginated vesicle (no non-enveloped virus fuses at the plasma membrane on entry), become wholly vesiculated and finally breach the vesicle membrane wholly or partially to gain entry to the cytoplasm or organelle (**Fig. 1**).

However, this simple outline belies a complexity of mechanism that is still the subject of active investigation: what does the virion sense, using which capsid components, to initiate vesicle exit, what conformational changes accompany entry, how is the necessarily unstable state of being primed for uncoating balanced with the need for virion stability, and not least, how does a large, often charged virus particle deform, dissolve or pass through a hydrophobic lipid bilayer. In addition, the act of uncoating exposes the virus nucleic acid to the cellular environment where it may be degraded or engaged by sensors of the innate immune system. This step must therefore be as quick as possible to minimize the potential danger to virus replication. The overall process is quite well understood for some viruses although as ever in virology, diversity abounds. For example, extensive membrane breaching studies have been completed with small, easily grown model viruses, such as Flock House Virus (FHV), an insect virus widely studied for the relationship between its structure and function. However, the identity of the receptor for this virus has never been defined, as is the case for most, if not all, viruses of insects. It is clear that the virus undergoes morphological change after contact

Fig. 1 Overview of non-enveloped virus cell entry. Virus attachment to the cell surface occurs via a range of receptors. Highly specific receptors tend to be tissue restricted cell surface proteins whereas less specific interactions occur on molecules that are widely distributed, such as sialic acid, heparins or integrins. In many cases the receptor remains unknown. Trapping to the cell surface leads to virus entry by one of the defined mechanisms of endocytosis which ultimately delivers the virus into a membrane bound vesicle. Many, but not all, vesicles become as acidic as they mature, triggering a conformational change in the virus which then breaches the membrane to enter the cell.

with a permissive cell surface but the identity of the molecules contacted has not been clearly described. By contrast, the entry reaction, once triggered, is well characterized. Thus, the precise understanding in one part of the entry process is offset by a lack of detail in another, a situation that is typical across the non-enveloped virus group as a whole.

Simple Non-Enveloped Viruses

While no virus is simple, non-enveloped viruses with a single capsid shell arguably have less complexity to deal with during the entry process as once the capsid is disrupted the genome can leave. For many classically studied examples, initial cell contact is via a specific receptor, an example being use of members of the immunoglobulin superfamily in the case of many picornaviruses (small round viruses with positive sense single stranded RNA genomes). Poliovirus uses CD155 whereas classical rhinoviruses use intercellular adhesion molecule-I, ICAM-I. The enteroviruses (those picornaviruses that infect in the gastrointestinal tract) use a range of receptors, for example both human scavenger receptor class B, member 2 (SCARB2) and P-selectin glycoprotein ligand-1 (PSGL1) are ligands for EV71 with SCARB2 acting as the critical entry molecule while both a general receptor, sialic acid, and the neuron specific intercellular adhesion molecule 5 (ICAM-5) act as receptors for enterovirus D68. Rhinovirus C, an emerging respiratory pathogen, uses cadherin-related family member 3 (CDHR3) and, in a very clear example of the link between receptor use and pathology, single nucleotide polymorphisms (SNP) in CDHR3 associated with asthma and wheezing in children also mediate the level of virus binding. Similarly, SNPs in the presumed hepatitis A virus receptor, T-cell immunoglobulin and mucin domain 1 (TIM-1), have been linked to enhanced virus entry and the severity of infection although in this case TIM-1 also functions as a known immune signaling molecule so the link to solely virus induced pathology is less clear cut. A specific receptor, junctional adhesion molecule 1 (JAM-1) can act as receptor for some caliciviruses but for others a general carbohydrate moiety is used while for other related small round RNA viruses, for example astroviruses, no defined receptors have yet been described. In other non-enveloped viruses too, a range of both highly specific and more general receptors are utilized to locate the virus to the cell surface. Parvoviruses, small round DNA viruses, use both carbohydrate binding, principally to sialic acid, and distinct protein receptors such as the transferrin receptor (TfR) to attach to the cell, and other small DNA viruses such as the papillomaviruses also demonstrate binding to both general and specific receptors, heparan sulfate and members of the integrin family of cell surface proteins respectively. There remain also many cases of unknown receptor usage across the non-enveloped virus group as a whole, sometimes through lack of experimentation but in other cases because no clear candidate has emerged, despite considerable experimental effort.

Notwithstanding the diversity of primary contacts, location to and active engagement with the cell surface of a permissive cell leads to uptake of virions into the cell by one of three well described mechanisms, macropinocytosis, clathrin mediated endocytosis and caveolin mediated endocytosis. Macropinocytosis is an actin-dependent uptake mechanism in which a membrane ruffle engulfs the virus particle, clathrin mediated endocytosis uses clathrin coated pits at the plasma membrane, often containing large receptor molecules, while endocytosis in caveolae use the protein caveolin as mediator of invagination of a cholesterol rich membrane, also enriched with large protein receptors (Fig. 2). Viruses using defined protein receptors will more commonly use one of the latter two mechanisms of entry although a mixed route of entry is not uncommon. Vesicles trafficked by one of the former two mechanisms will migrate, mature or merge with others in the cell cytoplasm and change the environment, notably the intra-endosomal pH, that surrounds the vesiculated virus, to trigger conformational changes that enable vesicle escape. Viruses entering via the caveolae route tend not to become acidified but are nonetheless trafficked to other organelles on cell entry.

In contrast to the diversity of entry routes, there is an emerging consensus on the shared features that describe the conformational change that many viruses undergo as a result of the changed environment of the endosome. To bind to, traverse or rupture the cellular membrane the engulfed virus must become more hydrophobic and this is achieved by the revelation of a peptide or protein containing hydrophobic residues often arranged as an amphipathic helix. Here, the canonical studies on FHV have provided a model. FHV assembles from 120 copies of the ~400 amino acid capsid protein, protein α , arranged as an icosahedral shell of 60 trimers. Following assembly the α protein cleaves autocatalytically to form capsid protein β and peptide γ , ~360 and ~40 residues respectively, the latter of which contains an amphipathic helix in the N-terminal half of the molecule and three phenylalanine residues at the C terminus. The γ peptide is located on the inside of the capsid following its release from protein α although it is transiently exposed by a process termed particle breathing, a reversible process by which the virus samples the environment before committing fully to uncoating. When it encounters acidic pH however, or exceptionally following contact with the receptor itself, the γ peptide is fully externalized via changes in capsid conformation and acts to destabilize the vesicle membrane. The mechanism of membrane destabilization is likely to be detergent-like as holes of 50–500 nm have been detected in the membrane following incubation with isolated peptide γ , easily sufficient to allow the two positive strand RNA molecules of 4.5 kilobase pairs, which constitute the virus genome, to pass through. This model, a maturation dependent cleavage of the capsid to generate a protein that is required for cell entry applies also to other groups of small non-enveloped viruses. In the picornaviruses, assembly requires 60 copies of each of three related proteins, VP0, VP1 and VP3, but within the newly assembled shell the VP0 protein is cleaved further, again autocatalytically, to generate VP2 and VP4, the latter of which is required for membrane permeabilization. VP4 is myristoylated and this post translational mechanism, which adds a long chain hydrophobic moiety to the N-terminus of the protein, is required for the entry reaction. As for the γ peptide of FHV, VP4 is predominantly found on the inside of the mature virus particle although its N-terminus is also transiently exposed by virion breathing. Following receptor triggering and/or low pH however, the particle undergoes irreversible change, which results in an opening at the 2-fold axis of symmetry and the emergence of VP4, which locates to the proximal membrane to form a pore through which the genome RNA can

Fig. 2 The defined uptake mechanisms of virus following receptor binding. Viruses enter cells to become enclosed in a vesicle by the same processes cells use to capture other cargo. They may use more than one pathway depending on the receptor bound. Pathway 1 involves the canonical acidified vesicle that follows macropinocytosis. Pathway 2, possibly the most widely used virus entry pathway, uses clathrin coated pits which subsequently may also become acidified. In both cases viruses must escape the vesicle during its maturation and before it fuses with the lysosome. Pathway 3 uses membrane patches enriched in certain lipids and different adapter proteins, caveolins, to mediate the inward budding process. Although some caveolae may also follow the endocytic route to a lower pH, an alternate non pH-mediated pathway via the formation of large caveosomes can lead to delivery of part disassembled viruses to other cellular compartments, such as the endoplasmic reticulum.

pass. The N-terminus of VP1 also emerges during this process and may serve to anchor the opening virion to the membrane allowing VP4 to function wholly in genome release. A somewhat similar mechanism was recently shown to operate also in the caliciviruses, small round viruses causing respiratory and gastrointestinal infections, where a minor capsid protein, VP2, forms a funnel-like pore extending away from the 3-fold axis of symmetry of the viral icosahedral structure following receptor engagement. The distal end of the VP2 structure is very hydrophobic and is assumed to embed in the host membrane to facilitate genome release into the cytoplasm through the funnel.

For some small non-enveloped DNA viruses the precise mechanisms of entry remain debated but the underlying principles leading to disassembly remain recognizable. Entry for viruses such as human papilloma virus, and the related polyoma viruses, is via the caveolae pathway leading to an endosome that also becomes acidic as it matures. Virus escape is not directly into the cytoplasm but rather into the endoplasmic reticulum (ER) as the virus must access the nucleus for replication and the continuity of the ER with the outer nuclear membrane provides a directly accessible route. There is conflicting data on exactly when and to what extent the virus dissociates but it is clear that there is a role for pH as well as for proteolytic enzymes, all present in the caveolin mediated vesicles. A role for host chaperones, particularly those that function as redox exchangers, and possibly a number of other trafficking molecules, has also been described. Together, their actions result in the loss of the major capsid protein VP1, leaving the minor capsid protein VP2 still associated with the genome. It is the VP2-genome complex that completes the trafficking process and enters the nucleus, probably when the nuclear membrane dissolves at cell division. The somewhat smaller and simpler parvoviruses, a member of which, adeno-associated virus (AAV), is in widespread use as a gene delivery vector, follow a similar pathway. A mix of specific (large protein) and general (sialic acid) receptors mediate the initial contact, depending on the strain of virus used, leading to virus uptake into endosomes predominantly via the clathrin dependent pathway. As for the papillomaviruses the precise stage at which endosomal escape takes place and the exact triggers that enable it, are poorly defined. Nevertheless, roles for a low pH acid activated proteolysis have been reported which together modify the capsid to allow membrane breaching. In a manner similar to the particle breathing noted for FHV and the picornaviruses, the N-terminus of capsid protein VP2 tests the environment, progressively increasing virus porosity in the endosomal environment until the N-terminus of VP1 protrudes from the five-fold vertices of the capsid. The virus does not encode a distinct lytic peptide, perhaps as a consequence of the limited coding potential associated with a small genome, but the VP1 protein contains a phospholipase A2-like domain whose activity is essential for endosomal escape. The overall process appears to be inefficient however, with many virus particles failing to escape the endosome and being delivered to the lysosome where they accumulate and degrade. Processing of the parvovirus capsid in the endosome is necessary as it equips it for engagement with cellular factors required for transport to the nucleus, principally the microtubule network and its associated motors, and direct injection of the virus into the cellular cytoplasm fails to recapitulate the entry reaction and so does not lead to a productive infection. As far as has been described, entry for circoviruses, small viruses with circular single stranded DNA genomes, is similar, clathrin mediated uptake after which viral antigen is found accumulated in

the lysosome. This implies that escape of the circular DNA genome must occur before this point but there is little detail of the mechanism involved beyond the mapping of a nuclear localization signal in the N-terminus of the single capsid protein of the virus.

Complex Non-Enveloped Viruses

Non-enveloped viruses with multiple layers face an additional dimension of challenge in that uncoating is often only partial, either to protect the nucleic acid from the sensors of innate immunity or because a second step is required before the replication cycle can begin, for example transport to the nucleus. In these cases the virus must arrest the process of disassembly before the genome is exposed and a core or sub-core is what enters the cytoplasm or other cellular compartment. As for the simpler viruses, primary contact with the cell can be highly specific via defined receptors or general via electrostatic charge or glycan interaction. For most human adenoviruses, large icosahedral DNA viruses with a linear double-stranded DNA genome, the human receptor is CAR, the Coxsackie and Adenovirus Receptor, a member of the immunoglobulin superfamily involved in cell to cell contact. A subset of adenoviruses also use CD46, another Ig superfamily member and some reports have also noted other receptors or attachment factors, including sialic acid. For the *Reoviridae*, complex multi-layered viruses with segmented double-stranded RNA genomes, several receptors have been described. For orthoreovirus (10 dsRNA segments) a single cellular tight junction protein, JAM-A, acts as viral receptor followed by association with various carbohydrates, including sialic acid, present on cell surface glycoproteins and glycolipids, which act as co-receptors. For the related rotaviruses (11 dsRNA segments), widely studied as they are a primary cause of childhood gastrointestinal disease, general and specific receptors again feature. Binding to the cell surface by some strains of rotavirus can be prevented by treatment with neuraminidase, which strips sialic acid from glycan chains, showing that sialic acid is a binding factor, but other sugars including those that occur internally can also act as binding sites. Some of these glycans make up the histo-blood group antigens and human rotaviruses can be distinguished by which of these antigens, H-type or A-type, they bind. More specific receptors are also used and many candidates have been described for various rotavirus strains including cell surface integrins and the ubiquitous chaperone heat shock cognate protein, hsc70. Tight-junction proteins, including JAM-A as used by reovirus, are also used by some rotavirus strains. For the orbivirus genus of the *Reoviridae*, insect viruses that nonetheless infect mammalian species, no clear receptors have emerged. For Bluetongue virus, the type species of the genus and responsible for economically important disease in sheep and cattle, lectins that bind to cell surface sugars reduce infectivity consistent with use of a sugar as receptor and potential sialic acid binding sites have been noted in the structure of the outermost capsid protein, VP2. However, sugar blocking or removal does not abolish infection suggesting that other, so far undiscovered, receptors must exist including those on insect cells, which remain wholly unknown.

Following binding to the cell surface complex non-enveloped viruses are taken up by the same mechanisms as those discussed for the simple non-enveloped viruses with a tendency more towards the use of clathrin and caveolin mediated pathways rather than the macropinocytosis pathway. For adenovirus, an example of a large dsDNA virus, the precise entry process is complex. The receptor is contacted by the penton fiber, a distinct structure on the virus particle that extends from the vertex of the icosahedral shell and which, with the penton base, mediates the overall process of cell entry. The distal knob domain of the fiber binds to the initial receptor, CAR or CD46 while conserved RGD residues in a loop of the penton base protein bind to cell surface integrins which act as co-receptors. Engagement with integrins leads to fiber shedding, in part at the cell surface but more completely as the virus completes the clathrin-mediated endocytic pathway of entry. The role of endosomal acidification for adenovirus entry is equivocal with evidence both for and against and the final triggers of disassembly remain unclear but the process of membrane breaching is carried out by protein VI which becomes active at this time. Mirroring the simpler FHV example, protein VI is packaged into the assembling virus particle as a pre-protein attached to the hexon protein via its N-terminus. Cleavage of the pre-protein releases protein VI as part of the viral maturation process and, among other functions, it acts as the membrane lytic agent after receptor and integrin binding. It is a partially uncoated adenovirus that then enters the cytoplasm, engaging with the microtubule network to traverse the cell to the nuclear membrane where final disassembly occurs after docking with a nuclear pore.

For members of the *Reoviridae* too it is a core particle rather than the viral genome that enters the cytoplasm. Not, as in the example of adenovirus, to facilitate later association with other cellular components or organelles, but to prevent the dsRNA genome from triggering the innate immune response. Double-stranded RNA is one of the most powerful inducers of the host interferon response, being recognized by multiple sensor proteins including toll-like receptor (TLR) 3 in the endosome and protein kinase R, MDA-5 and RIG-I in the cytoplasm. Clearly, revelation of the dsRNA genome by any member of the *Reoviridae* on entry to the cell would curtail infection very quickly. Receptor mediated location of *Reoviridae* members to the cell surface by one or more of the receptors discussed leads to internalization, in most cases via the clathrin mediated entry pathway as suggested by inhibition of virus replication by clathrin pathway inhibitors, although macropinocytosis mediated entry has also been observed. For orthoreovirus, the virus outer capsid protein sigma 1 mediates cell attachment and uptake. The subsequent acidification of the endosome does not lead to immediate conformational change in the capsid but to activation of an acid dependent cysteine protease, which degrades another major outer capsid protein sigma 3, to reveal the hydrophobic protein mu 1, also a component of the outer capsid. Further degradation of mu 1 essentially removes the outer capsid completely and in doing so, generates mu 1 derived hydrophobic peptides, which then mediate endocytic escape of the now denuded core into the cytoplasm. In this case the mechanism of membrane breaching must be by pore formation as the core is still large, 50–60 nm, and passes intact into the

cytoplasm, the dsRNA genome still safely surrounded by core protein lambda 1. Rotaviruses use a somewhat similar pathway although human and animal rotaviruses differ in their uptake mechanisms, clathrin mediated or not, and the receptors they use. Within the endosome rotavirus VP4 protein, which with VP7 makes up the two outer capsid proteins of the triple layered virus, is cleaved to form VP5* and VP8* with VP5* acting as the membrane active component. Through the use of tracker dyes that respond to the immediate cellular environment significant detail of the process has been accrued. Following engulfment, the particle begins the morphological changes required to escape the endosome almost immediately and particles that are still resident when the endosome becomes acidified do not complete the process. Calcium concentrations vary markedly between the endosomal space and the cytoplasm and calcium ions are also present in the complete virus particle where they stabilize the VP7-VP7 interactions in the outer capsid. The concentration of these ions drops quickly in a virus loaded endosome as a result of VP5* mediated membrane perturbation and the lower levels lead to a destabilized VP7, loosening the entire outer capsid layer. The loss of both VP4 and VP7 produces the double layered particle, the DLP, which is the form of the virus that enters the cytoplasm, the whole process taking as little as 10 min to complete. Entry is accompanied by activation of virus transcription so the loss of the outer capsid must transmit a signal to the virion interior to boot-up the resident polymerase. Recent cryo-EM structures of the rotavirus polymerase in situ come close to explaining how this is achieved although some detail remains unclear.

In the case of Bluetongue virus, a multilayered arbovirus with a ten segment dsRNA genome, no clear receptor has emerged beyond the observations that lectins antagonize virus uptake by mammalian cells and that sialic acid binding sites occur in the outermost capsid protein, VP2. However, these occur in the body of the large trimeric protein, not in the distal tip which is presumed to contact the cell surface first so initial contacts is likely to be with other cell surface molecules. In addition, insect cells, which are also a permissive host for virus replication, do not generally encode sialyltransferases, thus sialic acid binding cannot be the means of the location to the insect cell surface. Here, integrins have been suspected to play a role and integrin binding motifs occur in VP2 and in the inner capsid proteins, VP7, but overall the details of engagement with the insect cell surface remain unclear. A role for metal ions, in this case zinc, in capsid stability has also been shown following the description of a zinc finger motif in the structure determined for VP2. Mutation of the conserved residues within the motif destabilizes the virus, consistent with a physiological role. Uptake, at least in mammalian cells, is via the clathrin pathway and VP2 is shed in the early endosome, plausibly aided by the loss of the chelated zinc ions as the lower pH protonates the ligand residues of the zinc finger (Fig. 3). As the endosome matures and the pH drops further the second outer capsid protein VP5 undergoes extensive conformational change to promote the transfer of the inner particle, the virus core, into the cytoplasm. The VP5 structure obtained by high-resolution cryo-EM of virus particles at neutral pH is broadly globular with extensive amphipathic alpha helices that include a central coiled-coil

Fig. 3 Complex, layered virus entry as exemplified by the entry of Bluetongue virus. (1) The virus binds to unspecified receptors including sialic acid via its outermost capsid protein VP2 and the process of clathrin mediated uptake begins. (2) In the early endosome the pH drops and the VP2 protein loses structural integrity through the loss of chelated zinc ions, disengaging from the particle and possibly degrading. (3) Further acidification in the late endosome triggers a substantial conformational change in the VP5 protein which now binds the endosomal membrane. (4) Sufficient VP5 binding occurs to trigger membrane disruption and the beginnings of a pore in the vicinity of the virus particle. (5) The pore enlarges and the virus core passes through by an as yet undefined mechanism. The VP5 conformational change is irreversible and it is shed during the passage of the core. (6) The core is released to the cytoplasm where it immediately becomes transcriptionally active, triggered by a minor change in the inner capsid protein VP3. The fate of the residual endosome is unclear but the pore could close and the endosome continue its progress to the lysosome where any remaining virus proteins would be degraded.

alpha-helical bundle, reminiscent of the structures found in the fusion proteins of many enveloped viruses. The structure of the virus at low pH however fails to identify VP5 beyond a stub which remains in contact with the core, indicating that the majority of the VP5 chain is extended and flexible, consistent with extensive interaction with the endosomal membrane. Indeed, translocation of VP5 to the cell surface by an expression vector followed by an acid pulse leads to syncytium formation formally demonstrating its membrane fusion potential. As for rotavirus, recent high resolution cryo-EM structures of the virus core have located the virion polymerase, VP1, which similarly becomes active once the outer capsid has detached and the core particle is in the cytoplasm. In part this is the result of unblocking of the pores at the vertices so that solutes can enter and transcripts leave but the structure also suggests a more active signal in that a distinct contact between the N-terminus of the inner core protein VP3 and the polymerase acts to stimulate the resting structure into action (Fig. 3). This active cross talk between the final stages of uncoating and the initiation of virus replication confirms how important the entry pathway is. It is not enough just to enter the cell, that entry reaction must follow certain defined steps if the infection is to become a reality.

Exploitation of the Virus Entry Pathway

As the description of cell entry for a range of viruses has indicated, the mature virion, that is a virion that is capable of undergoing the entry reaction, is metastable. Given the right cues the virus will disassemble and there is very little wriggle room between the two extreme states, that is, primed for entry and entered. This presents a known difficulty in some virus applications, notably vaccine preparation and storage. Here the long-term storage of virus can lead to premature disassembly as the dynamic particle breathing that almost all viruses undergo can eventually tip the balance in favor of full activation and lead to an irreversible loss of infectivity or immunogenicity. In poliovirus for example, the preparation of vaccine involves a measure of the H (heated) and N (neutralizing) antigenic forms with only those preparations with high N levels deemed acceptable for vaccine use. The H form, which can be fully induced by heating the virus, is a slightly expanded particle, which has initiated the early stages of the entry reaction and, in doing so, abolished the capsid features that are necessary to induce neutralizing antibodies. As noted, the maturation reaction for many viruses, often a protein cleavage which primes the virus for entry, is a very late event in the replication pathway and usually accompanies genome packaging. This means that recombinant routes to vaccine production, by the formation of virus-like-particles for example, run the risk of failing to mimic the final maturation event as no genome is ever packaged. As a result of this concern a form of recombinant vaccine, safe and manufacturable outside of containment facilities, may not be as immunogenic on a weight for weight basis as the authentic virus. Recombinant approaches to the production of other picornavirus vaccines, Foot and Mouth Disease Virus for example, face similar challenges and active capsid engineering to increase the stability of the empty capsids is required to ensure that the recombinant product is fully immunogenic. Understanding the details of the entry reaction can therefore have important consequences in a number of areas of applied virology (Fig. 4). Beyond vaccine development, a number of other areas of application similarly depend on a detailed understanding of the entry reaction. Several non-enveloped viruses are in active development as oncolytic agents and as mediators of gene transfer. In these cases the recombinant virus, acting purely as a vector in the latter case, must enter target cells efficiently to fulfill its purpose. As noted, parvoviruses are often destroyed on entry as they fail to escape the endosome before fusion with the lysosome meaning that their genetic cargo never reaches the nucleus to enable transcription and the production of a therapeutic effect. In consequence, very large doses of gene delivery vectors such as AAV are needed to ensure the delivery of a sufficient genetic payload for therapy and, as a result, the yields of a number of gene therapy vectors represent a current bottleneck, for which improvements in the cell entry pathway could, in part, address.

A final area of application where study of the entry mechanism of non-enveloped viruses may benefit application is in the development of antiviral drugs. As described, the entry pathway is, in essence, a series of programmed virus specific changes

Fig. 4 Points at which the cell entry pathways of viruses could be open to exploitation. The metastable state of the virus can be modified by recombinant capsid engineering to improve vaccine stability. Receptor binding can be modified to repurpose viruses as gene delivery agents with altered tissue tropism. Disassembly inhibitors are already a reality and more could be developed, locking the virus in a form that cannot progress to infection. As revealed by recent structural studies the activation of a complex virus core depends on the completion of the correct entry process leading to the possibility that this too could be a target for inhibition once detailed knowledge of the activation steps have been obtained.

engendered at the appropriate time by contact with host factors. It follows that blocking any one of these obligatory changes would block virus infection. In the picornaviruses precisely such a block has been demonstrated by the isolation of compounds that prevent the stages of the entry reaction that follow initial receptor binding. In some, but not all, picornaviruses one of the three proteins that make up the final capsid shell, VP1, contains a hydrophobic cavity that is naturally occupied by a long chain fatty acid molecule picked up from the cell during assembly. These “pocket” factors provide a stuffer function which prevents the cavity from collapsing and lie immediately underneath the VP1 residues that contact the receptor. The ejection of such factors follows engagement with the cell receptor and initiates the disassembly reaction. A series of synthetic compounds have been isolated that bind the pocket far more tightly than their natural counterparts, such that they cannot be jettisoned when the virus engages with the receptor. As a result the entry reaction is aborted and the drugs concerned exhibit powerful antiviral activity. To a greater or lesser extent all picornaviruses which make use of pocket factors can be inhibited by such compounds, which have broad antiviral properties for this family of viruses. The exemplar illustrated by pocket factor mimic compounds demonstrates that the entry pathway of non-enveloped viruses is a *bona fide* target for antiviral drug development and that it offers the possibility of broadly reactive compounds, one of the most sought after goals in the field of antivirals.

Concluding Remarks

The diversity of the global virome might suggest a myriad of entry pathways to allow infection of any cell of any organism in any phylum. Perhaps surprisingly, this is not the case and while the precise details of entry naturally vary depending on the virus, the principles of the process are shared. Recently, transient retention of a membrane was demonstrated for some non-enveloped viruses, Hepatitis A virus serving as the exemplar, but these membranes are not impregnated with any virus protein so cannot act in membrane fusion. Rather they appear to be a cloaking mechanism to hold off immune recognition for as long as possible, enabling the virus to disseminate within the host more efficiently. Thus, for the non-enveloped viruses the possibility of simply merging membranes together to enter a cell is ruled out and particular mechanisms must have evolved to deal with crossing what is otherwise a controlled and impermeable barrier. Immobilization on the cell surface is a necessary first requirement that is met by engagement with a number of molecules that act as virus receptors. A range of molecular types serve this purpose with a loose correlation between the selectivity of binding and virus tropism, high affinity protein interaction being used to gain access to a particular tissue while common cell surface components tend towards a distributed infection. In some cases the binding to the receptor may trigger virus conformational change but more commonly this requires entry into, and detection of the environment within, an endosome. The key triggers, depending on the endocytic route taken, are a lowering of pH and or the activation of proteolysis. The type of lipid within the endosomal membrane may also serve as a cue to alert the virus to a suitable environment for disassembly. Disassembly invariably results in the exposure of a more hydrophobic protein or peptide that is lipophilic, a process that is irreversible. The precise mechanism of membrane disruption that these proteins enable remains unclear in many cases. For some, such as the picornaviruses, an intermediate of the capsid attached to the endosomal membrane and an asymmetrical release of the genome through a portal is relatively well defined but in other cases a residual virion structure, often close to the size of the original virus, must traverse the membrane intact. How the necessary pore is formed and whether it closes behind, to maintain immunological elusiveness perhaps, is not known. The complexity of biological membranes is only partly reproduced by the use of *in vitro* systems, limiting the experimental approaches that can be applied but the increasing use of newer technologies, such as cryo-EM tomography, which is capable of visualizing the act of fusion, will surely shed light on these intricate and fast interactions. Many details of entry are known and as the pathways and triggers become better described so the opportunity to exploit them will increase. For the virus, the potential for replication lies at the end of a successful entry reaction, for the observer the opportunity to prevent it. It is a curious fact that the start of something for one could spell an opportunity for its control by another.

Glossary

Enveloped viruses Viruses that are surrounded by a lipid bilayer derived from host cell membranes generally acquired at the budding stage.

Glycoprotein Proteins which contain oligosaccharide chains covalently attached to amino acid side-chains. In general, fusion glycoproteins are N-glycosylated on asparagine residues.

Endocytosis A cellular process in which material is internalized by the cell. The cargo to be internalized is progressively wrapped by a cellular membrane which then buds off inside the cell forming a vesicle containing the material.

Fusion peptide or loop Short hydrophobic motifs in a viral fusion glycoprotein which interacts with the cellular membrane to initiate the fusion process. When they are amino terminal, they are referred as a fusion peptide whereas when they are internal, they are referred as a fusion loop.

Hemifusion An intermediate stage during membrane fusion that is characterized by the merger of the outer monolayers but not the two distal (inner) monolayers.

Fusion pore Small opening that allows flux between two membrane bound compartments. Fusion pores form at a stage of membrane fusion that follows hemifusion and finally widen, leading to full fusion.

Prefusion conformation Conformation of the fusion glycoprotein at the viral surface after priming but before fusion triggering.

Postfusion conformation Conformation of the fusion glycoprotein at the end of the fusion reaction.

Priming Proteolytic cleavage in the fusion glycoprotein precursor or in an accompanying protein which brings the fusion glycoprotein into a state capable of responding to a fusion trigger.

Triggering Triggering induces the structural transition from the prefusion to the postfusion conformation. Usual triggers are receptor interaction and low-pH environment.

Introduction

Enveloped viruses are surrounded by a membrane made of a lipidic bilayer. They are encountered in living organisms of the three domains of life. In most cases, their envelope is acquired at the end of the cellular viral cycle at the budding stage and is derived from the host cell membrane. It contains phospholipids and cholesterol, and includes virally encoded transmembrane proteins. In general, cellular membrane proteins are largely excluded from the viral envelope.

Entry of enveloped viruses into host cells requires binding of the virus to one or more receptors present at the cell surface, followed by fusion of the viral envelope with a cellular membrane which allows the release of the inner content of the virion, including its genome, into the host cell cytoplasm for the subsequent steps of infection.

Membrane fusion, being key in several biological processes, has been well studied and, in all the systems that have been characterized, it has been shown that the fusion of two membranes facing each other proceeds via local dehydration and formation of an initial stalk that is a local lipidic connection between the outer leaflets of the fusing membranes. Radial expansion of the stalk induces the formation of a transient hemifusion diaphragm (i.e., a local bilayer made by the two initial inner leaflets). The next step is the formation of a pore in the fusion diaphragm. The initial pore is small and may open and close repeatedly

Fig. 1 Stages of membrane fusion of two lipid bilayers according to the stalk-pore model.

before its enlargement that leads to complete fusion (**Fig. 1**). Although membrane fusion can occur spontaneously, there are energetic barriers that have to be overcome at different steps of the process, the highest one being encountered during the expansion of the initial fusion pore. Therefore, in living organisms, there are fusion machineries which catalyze membrane fusion so that it occurs at the right place and time.

In the case of enveloped viruses, this machinery is constituted by virally encoded transmembrane proteins. The best characterized viral fusion machineries are the fusion glycoproteins of eukaryotic viruses which are transmembrane type I glycoproteins. After cleavage of their amino terminal signal peptide, the mature fusion glycoproteins have an N-glycosylated aminoterminal ectodomain anchored in the membrane by a single α -helical transmembrane segment. The C-terminal intraviral domain is of variable size and may interact with internal proteins of the virion and/or regulate the fusion activity.

Upon interaction with specific triggers such as viral receptors or a low-pH environment, viral fusion glycoproteins undergo a huge conformational change from their prefusion (or native) toward their postfusion (or final) conformation. During the structural transition, they expose hydrophobic motifs (the so-called fusion peptide or fusion loops) that interact with one or both of the participating membranes, resulting in their destabilization and initiation of the fusion reaction. When the hydrophobic motif is amino terminal, it is referred as a fusion peptide whereas when it is internal, it is referred as a fusion loop.

Based on their structure and common structural motifs, viral fusion proteins have been classified into three distinct classes.

General Considerations

Viral Fusion Site in the Cell

For eukaryotic viruses, fusion can take place either at the plasma membrane or after endocytosis of the viral particle in the endosome.

Fusion of several viruses belonging to the Herpesviridae, Retroviridae, Paramyxoviridae family and some members of the Coronaviridae occurs at the plasma membrane. For those viruses, the fusogenic conformational change is triggered by receptor recognition. For Retroviridae and Coronaviridae, the fusion glycoprotein is also involved in receptor binding whereas, for Paramyxoviridae and Herpesviridae, another viral glycoprotein promotes receptor recognition.

For other viruses, fusion occurs after particle endocytosis. In the endosome, fusion is often triggered by the acidification of the lumen of the vesicle. Indeed, low pH alone is able to trigger fusion of rhabdoviruses (such as rabies virus or vesicular stomatitis virus-VSV-), orthomyxoviruses (such as influenza virus), bunyaviruses (such as Ukuniemi virus), alphaviruses (such as Semliki forest virus-SFV-), flaviviruses (such as Dengue virus-DENV- and tick borne encephalitis virus-TBEV-) and baculoviruses. Depending on the pH threshold required for triggering the fusion glycoprotein conformational change, fusion occurs in the early endosomes (pH $\sim$ 6.5) or in late endosomes (whose pH can be as low as 5). As in other pH-sensing proteins, histidine residues often play a key role as their side chain pKa is around 6.5 and their protonation destabilizes the prefusion conformation.

For some other endocytosed viruses, such as avian sarcoma leucosis virus (an alpharetrovirus), Ebola virus (EBOV, a filovirus) or Lassa virus (an arenavirus), fusion activation requires both receptor binding and low-pH. It is worth noting that, in some cases, the cellular protein triggering the conformational change of the fusion glycoprotein is only located in the endosome and, therefore,

is different from the receptor leading to virion endocytosis. Finally, for viruses including severe acute respiratory syndrome coronaviruses 1 and 2 (SARS-CoV-1 and SARS-CoV-2), Middle East respiratory syndrome coronavirus (MERS-CoV) and respiratory syncytial virus, low pH is not required for fusion but endocytosis is necessary for the activation of the fusion glycoprotein by endosomal proteases (such as furin or cathepsin).

Finally, the dichotomy between viruses fusing at the plasma membrane and those fusing in the endosome is not that strict inside a viral family (e.g., Retroviruses and coronaviruses) and even for a single virus the place of fusion may depend on the cell type (e.g., for some herpesviruses).

Specific Lipid Requirements

In vitro fusion systems between viral particles and artificial membranes of defined composition have revealed the absolute requirement of some lipids for some viruses. The best example is SFV for which both cholesterol and sphingomyelin have to be present in the target membrane for fusion to occur.

In several other cases, although not an absolute requirement, presence of some lipids enhances the fusion reaction. This is the case for VSV, DENV and Uukuniemi virus for which fusion is enhanced by presence of anionic lipids such as lysobisphosphatidic acid (LBPA) or bis(monoacylglycerol)phosphate (BMP) that are both late endosome specific phospholipids.

Structure of Viral Fusion Glycoproteins

Class I fusion glycoproteins

Influenza HA, the prototype of class I fusion glycoproteins

The first crystal structure of a viral fusion glycoprotein ectodomain to be determined was that of the influenza virus hemagglutinin (HA), isolated after limited bromelain digestion from purified virions. HA is synthesized as HA0, a precursor molecule cleaved by a cellular protease to produce HA1, a sialic acid binding domain involved in receptor recognition, and HA2, a membrane-anchored fusion domain. HA0 cleavage primes the protein for the low pH-induced fusogenic conformational change.

In its prefusion conformation, HA is a homotrimer, each protomer consisting of an HA1 and an HA2 chain connected through a single disulfide bridge. In the prefusion structure, most of HA2 forms an elongated trimeric coiled coil to the top of which HA1 is tethered. The amino-terminal extremity of HA2, which has been generated by cleavage of HA0, is highly hydrophobic and constitutes the fusion peptide which is buried at the trimeric interface (Fig. 2(A)).

After low-pH exposure, HA undergoes a huge structural transition which results in the loss of HA1–HA2 interactions and dissociation of the HA1–HA1 interface which stabilizes the prefusion structure. Globally, HA low-pH-induced conformational changes result in a dramatic refolding of HA2 while HA1 keeps its tertiary structure. During the refolding, a long loop in native HA2 converts to a helix, increasing the length of the central coiled coil at its N-terminal end. This movement translocates the fusion peptide toward the head of the molecule, where is located the target host membrane. The structural transition is completed by a relocation of the carboxyterminal membrane anchor through a foldback mechanism to the amino-terminal end of the rod-shaped molecule. This results in the so-called hairpin conformation in which the transmembrane segment and the fusion peptide are in close proximity at the same end of the elongated molecule, as expected at the end of the fusion process when the viral and endosomal membranes have merged (Fig. 2(A)).

Class I common characteristics

Several fusion glycoproteins have similar features to those of HA. Together, they define the characteristics of class I fusion glycoproteins. Besides HA, this class includes the fusion glycoproteins of Paramyxoviridae (e.g., parainfluenza and measles viruses), Pneumoviridae (e.g., respiratory syncytial virus), Retroviridae (e.g., HIV, Avian sarcoma leukemia virus-ASLV-, Murine leukemia virus), Filoviridae (e.g., EBOV), Arenaviridae (e.g., Lassa virus) and Coronaviridae (e.g., SARS-CoV, MERS-CoV), these viruses are usually not icosahedral.

Class I fusion glycoproteins are trimeric in both their pre- and post-fusion conformation. They have an internal, frequently furin-like, cleavage site. The cleavage is required for priming them to the prefusion conformation that will be capable of undergoing the fusogenic

Fig. 2 Class I fusion glycoproteins. (A) Influenza hemagglutinin (HA) structures. Left part: Ribbon representation of HA trimer and HA2 protomer in the prefusion conformation. The sialic acid binding domain (HA1) subunits are colored in gray and the HA2 fusion proteins are colored in blue and red. The amino-terminal extremity of HA2 constitutes the hydrophobic fusion peptide (FP, colored in magenta) which is buried at the trimeric interface in this conformation. Right part: Structure of HA2 trimer and protomer in postfusion conformation. The positions of the TM domain and of the fusion peptide (FP) are indicated on the postfusion protomer. The HA2 segment that refolds into an helix is colored in cyan in both conformations. (B) Trimeric hairpins structures of several class I viral fusion proteins. Top and side views of the fusion proteins from 6 different viruses are shown: The N-terminal coiled-coil core is colored in blue and the C-terminal domain reaching the transmembrane domain is in red. In all those structures, the trimer-of-hairpins conformation brings the N- and C-termini (corresponding to the position of the fusion peptides and transmembrane domain respectively) into close proximity. (C) Ribbon representation of the prefusion structures of HIV-1 env and EBOV GP fusion proteins (side and top views, each protomer is depicted in a different color). (D) Ribbon representation of Paramyxovirus, Pneumovirus and Coronavirus viral fusion proteins structures in their pre and postfusion conformation. For each structure, a side and a top view are presented and each protomer is in a different color. All those structures have an extended common core indicating that they evolved from a common ancestor. On each panel, the position of the membrane with respect to the side view of the fusion glycoprotein is indicated by a green line. For each structure, its PDB code is indicated in red.

structural transition in response to a specific fusion trigger. The transmembrane C-terminal fragment resulting from the cleavage is the fusion subunit (corresponding to influenza HA2) which bears at or near its N-terminal end a stretch of about 15 hydrophobic amino acids which constitutes the membrane interacting motif.

In the prefusion state, the N-terminal and C-terminal fusion subunits remain held together by either a disulfide bond (as in influenza HA) or non-covalent interactions (e.g., in HIV Env). The fusion peptide is buried at a protein-protein interface.

In the postfusion state, the fusion subunit is refolded into a trimeric coiled coil at the N-terminal end of which are located the three fusion peptides, now solvent exposed, and in the grooves of which are packed, in an antiparallel manner, the segments abutting the transmembrane region. In this conformation, the protomer shape is thus an elongated hairpin-like structure with the fusion peptide and the transmembrane domain located at the same end (**Fig. 2(B)**).

A class I signature is the presence of heptad repeats (HRs) in the amino-acid sequence of the glycoprotein. HRs are made of a repeating pattern of seven amino acids *abcdefg* where *a* and *d* are hydrophobic residues. A first HR region (named HRA or HR1) is located immediately downstream of the fusion peptide and forms the central trimeric coiled coil. It is often accompanied by a second (named HRB or HR2) located in the C-terminal part of the ectodomain that constitutes the helices positioned in the groove of the central coiled coil.

Except for this common structural motif, the structure of class I glycoproteins are quite different and it is not clear whether these proteins have evolved from a distant common ancestor (**Fig. 2(C, D)**). However, the structures of the fusion glycoproteins of Coronaviridae, Pneumoviridae and Paramyxoviridae share an extended common core implying that they have an evolutionary connection (**Fig. 2(D)**).

Class II Fusion Glycoproteins

TBEV E, the prototype of class II fusion glycoproteins

Glycoprotein E from TBEV, a member of the Flavivirus genus in the Flaviviridae family, was the first class II fusion glycoprotein of which a crystal structure was been solved.

The E protein folds co-translationally with a companion protein called prM. The heterodimeric association between E and prM is absolutely required for correct folding and transport of E. Immature virions are formed by budding of the genome-containing capsid into the lumen of the endoplasmic reticulum. prM and E are organized into an icosahedral lattice at the viral surface. Virion maturation involves a dramatic rearrangement of their organization at the particle surface. Finally, proteolytic cleavage of prM in the trans-Golgi network by a furin-like protease primes E for low pH-induced fusogenic conformational change and is therefore required for virion infectivity.

E displays a molecular architecture completely different from that of HA and other class I fusion glycoproteins (**Fig. 3(A)**). In its prefusion conformation, it forms an elongated antiparallel dimer, lying flat at the viral surface, and organized in an icosahedral lattice. The polypeptide chain of a protomer folds into three distinct domains. Domain I is a central β -barrel. Domain II is the fusion domain, it is elongated and also implicated in E dimerization. Domain III is located in the carboxyterminal part of the ectodomain and has an immunoglobulin-like fold. The internal fusion loop is located between two β -strands at the tip of the fusion domain and buried at the dimeric interface. Upon exposure to low pH, dimers dissociate and the protomers reassociate in a trimeric structure (**Fig. 3(A)**). The conformational change of a protomer is less impressive than that observed for class I viral fusion glycoproteins as there is little change in the secondary and tertiary structures of the three domains. Nevertheless, the interactions between the domains constituting a protomer are markedly different in the pre- and postfusion conformations. In particular, domain III, which is connected to the C-terminal part of the molecule, moves by about 35 Å toward the fusion loop. This movement redirects the polypeptide chain, so that the transmembrane segment is located near the fusion loop region at the same end of an elongated trimer that is now perpendicular to the membrane. Therefore, despite the different architecture of the proteins, the postfusion structure of E is reminiscent of the postfusion hairpin structure of class I fusion proteins.

Class II common characteristics

Other flaviviruses E glycoproteins (including DENV, West Nile, Japanese encephalitis and Zika viruses E) were subsequently shown to adopt a very similar structure. E1 glycoproteins of alphaviruses (including SFV, Sindbis and Chikungunya viruses) (**Fig. 3(B)**) and of rubella virus (previously considered together with alphaviruses as a member of the togaviridae family) (**Fig. 3(C)**) also have the same fold despite the absence of sequence similarity. This revealed that E and E1 derived from a common ancestor. The simplest explanation for this homology is that flaviviruses and alphaviruses, having both positive-stranded RNA genomes with very similar organization, share an ancient common ancestor.

More unexpectedly, the fusion glycoprotein Gc of some viruses belonging to the unrelated bunyavirales order (including Rift valley fever virus, RVFV, from the Phenuiviridae family and Hantaan and Puumala viruses from the Hantaviridae family), were also shown to be class II fusion glycoproteins (**Fig. 3(D)**). The prefusion structure of RVFV Gc is remarkably similar to that of flaviviruses E glycoprotein as it also forms head-to-tail dimers (**Fig. 3(D)**). This extreme similarity is not found in the spike architecture of the Peribunyaviridae (such as La Crosse, Schmallenberg and Bunyamwera viruses) which also belong to the bunyavirales order. Indeed, in addition to the class II fold, Peribunyaviridae Gc glycoproteins have two additional aminoterminal domains that are involved in the trimerization of the prefusion conformation.

Fig. 3 Class II fusion glycoproteins. (A) Ribbon representations of the dimeric prefusion conformation of TBEV E (left part) and of its trimeric postfusion conformation (mid. part). Right part: TBEV E protomer conformational change. The arrow indicates DIII movement toward the fusion loop in DII. (B) Ribbon representation of SFV E1 in its pre and postfusion conformations (C) Ribbon representation of rubella virus E1 in its trimeric postfusion conformation. Note that rubella virus E1 has two fusion loops (indicated by asterisks). (D) Ribbon representations of RVFV Gc head-to-tail prefusion dimer and of its trimeric postfusion conformation (right part). The two fusion loops are indicated by asterisks. The prefusion organization of RVFV Gc is remarkably similar to that of flaviviruses E glycoprotein. (E) Ribbon representations of EFF1 protein from *C. elegans* (left part) and structure of HAP2 from *Chlamydomonas reinhardtii* gamete fusion protein (right part) in their postfusion states. Note the absence of fusion loop at the tip of DII on EFF1. All class II glycoproteins have the same fold, made of a central domain DI (in red), a fusion domain DII (in yellow) and C-terminal domain DIII (in blue), which reveals that they derived from a common ancestor. Fusion loops, located at the tip of DII, are in pink. For each structure, its PDB code is indicated in red.

All class II viral fusion glycoproteins identified so far have the same structural organization into three domains as TBEV E. The target membrane interacting region is located at the tip of the fusion domain (domain II). It is in general monopartite (bearing a single fusion loop) but sometimes bipartite (bearing two fusion loops) as in the case of rubella virus E1 and RVFV Gc (Fig. 3(C and D)) and even tripartite in the case of hantavirus Gc. In the prefusion conformation, fusion loops are in general buried at a dimer interface.

Fig. 4 Class III fusion glycoproteins. (A) Ribbon representations of VSV G prefusion trimer and protomer (left part) and of VSV G postfusion trimer and protomer (right part). (B) Ribbon representation of HSV-1 gB, baculovirus GP64 and thogotovirus Gp in their post-fusion conformation (trimer and protomer). Color code: central domain (CD) is in red, pleckstrin homology domain (PHD) is in orange, fusion domain (FD) is in yellow, refolding segments R1-R4 are in cyan, C-terminal segment reaching the transmembrane anchor (R5) is in green. The position and length of segments R1-R5 for gB and GP64 and Gp are only postulated as the extent of the conformational change remains unknown. For each structure, its PDB code is indicated in red.

Class II viral fusion glycoproteins are synthesized and folded as a complex with a second viral envelope protein (prM for flaviviruses, E2 for alphaviruses, Gn for bunyaviruses) that plays a chaperone role. Proteolytic cleavage of this companion protein primes the fusion glycoprotein so that it is capable of undergoing the low-pH-induced fusogenic structural transition. In their native conformation, they form homo- (flaviviruses and phenuiviridae) or hetero- (alphaviruses) dimers that lie flat or nearly flat at the viral surface but also sometimes trimers (Peribunyaviridae) having a tripodal organization.

In most cases, in their prefusion state, class II fusion glycoproteins are organized in an icosahedral assembly at the viral surface. However, no icosahedral symmetry is detected on rubella virus particles although it cannot be excluded that the symmetry is disrupted during purification and manipulation of the virions. Icosahedral symmetry is also highly improbable for hantaviruses: at the surface of the virion, ordered patches of square-shaped assemblies with 4-fold symmetry are detected which are not compatible with icosahedral symmetry.

Finally, upon low pH exposure, class II prefusion oligomers dissociate and the fusion glycoprotein subunits reassociate in a trimeric structure. Similar to the structure of post-fusion class I proteins, the fusion loops and the transmembrane domains are then located at the same end of an elongated molecule that is now perpendicular to the membrane.

Several cellular fusogens have the class II fold

Remarkably, several eukaryotic proteins involved in cell-cell fusion have been found to possess the class II fold and, therefore, share a common ancestor with all class II viral fusion glycoproteins. This was initially demonstrated for the EFF1 (epithelial fusion failure 1) protein which catalyzes cell-cell fusion events required for the development of *Caenorhabditis elegans* (Fig. 3(E)). Later, the

class II fold was also found in *Chlamydomonas*, *Arabidopsis*, *Plasmodium* and *Tetrahymena* HAP2 proteins which mediate gamete fusion (Fig. 3(E)). In their post-fusion state, all those cellular fusogens form a trimer organized as the post-fusion trimer of class II viral fusion glycoproteins (Fig. 3(E)).

Despite the conservation of their folds, it is not clear whether those proteins all act similarly. Indeed whilst several HAP2 proteins have one or several fusion loops and probably mediate fusion in a manner similar to viral fusogens, EFF1 does not seem to have such a loop and has to be present in both membranes to catalyze their merger.

It is unclear whether the gene encoding the original class II fusion glycoprotein was present in a cellular or a viral genome. However, it is certain that there have been horizontal transfers of genes encoding class II fusion glycoproteins between viruses and their host (whatever the direction of this transfer) and/or between viruses during co-infections.

Class III Fusion Glycoproteins

VSV G, the prototype of class III fusion glycoproteins

The third class of fusion proteins was identified when the structures of the ectodomains of the fusogenic glycoproteins G of VSV and glycoprotein B (gB) of herpes simplex virus 1 (HSV-1) were determined. Their comparison revealed an unanticipated similarity between the structures of the two proteins, although no sequence similarity had been detected previously.

VSV G is involved in both membrane fusion and receptor recognition. It is the only class III fusion protein for which the X-ray structures of both the pre-fusion and post-fusion trimeric states have been determined (Fig. 4(A)). The polypeptide chain of G ectodomain folds into three distinct domains: the fusion domain (FD) is inserted in a loop of a pleckstrin homology domain (PHD) that is itself inserted in a trimerization domain (TrD) which is involved in G trimerization in both states. The domains are connected to each other by segments that change their conformation during G structural transition. Segments R1 and R4 connect TrD to PHD, while R2 and R3 connect PHD to FD. The TrD comprises a β -sheet rich region connected to the C-terminal segment (R5) of the ectodomain (Fig. 4(A)).

During the low pH-induced structural transition from pre- to post-fusion state, FD, PHD and TrD retain their tertiary structure but undergo large rearrangements in their relative orientation. In the context of VSV G trimer, the pre- and post-fusion states are related by flipping both FD and the C-terminal segment around TrD. The conformational change is driven by refolding of segments R1 to R5. At the end of the transition, in the post-fusion state, the core of the structure is organized in a 6-helix bundle, the trimeric core of which is made by the three TrD central helices (extended by the refolding of segment R4), whose grooves accommodate three lateral helices resulting in the refolding of R5 (Fig. 4(A)). This structural organization is obviously very similar to that of the central core of the post-fusion conformation of some class I viral such as EBOV gp2 and HIV-1 gp41.

On the other hand, the organization of VSV G FD is very similar to that of class II fusion proteins, although they have distinct topologies. Similarities include an extended β -sheet structure terminating in a three-stranded sheet at the tip of which are located two hydrophobic fusion loops. In the pre-fusion structure, in contrast to class I and class II fusion proteins, those fusion loops are not buried at an oligomeric interface but point toward the viral membrane.

A particular feature of VSV G which is shared with other rhabdovirus glycoproteins is that the low pH-induced conformational change is reversible. In fact, there is a pH-dependent equilibrium between the different states of G (i.e., the prefusion state, the post-fusion state and also monomeric conformations that are intermediates on the pathway of the structural transition) that is shifted toward the post-fusion state at low pH. This is a major difference with class I and class II viral fusion glycoproteins for which the pre-fusion conformation is metastable and, therefore, the fusogenic structural transition is irreversible.

Class III common characteristics

Besides VSV G and HSV-1 gB (Fig. 4(B)), fusion glycoproteins of other herpesviruses (including Epstein-Barr virus and cytomegalovirus) and other rhabdoviruses (such as rabies virus) also belong to the class III of fusion glycoproteins. The fusion glycoprotein gp64 of baculovirus and of thogoto virus Gp (an arbovirus member of the Orthomyxoviridae as influenza virus) have also been demonstrated to be class III fusion glycoproteins (Fig. 4(B)) and, on the basis of amino acid sequence alignment, it seems that it is also the case of the glycoprotein of bornaviruses.

All class III viral fusion glycoproteins identified so far are homologous and have the same domain organization as VSV G. They are encountered in viruses which have no common origin (negative-strand RNA and double stranded DNA viruses) which suggests that, as for class II fusion glycoproteins, at least some of them have been acquired by horizontal transfers. Thogoto virus Gp and baculovirus gp64 are extremely similar, suggesting a relatively recent gene transfer between those two arboviruses, whereas rhabdovirus glycoproteins are more distantly related to gB and gp64 suggesting a much more ancient separation.

As already mentioned, we do not know the prefusion conformation of class III glycoproteins except for VSV G. However, low resolution envelopes of herpesviruses gB in their putative prefusion state have been obtained by cryotomography. They strongly suggest that the prefusion state of gB has an organization which is similar to that of VSV G.

Finally, whereas rhabdovirus G, Thogoto Gp and baculovirus gp64 are triggered at low pH, herpesvirus gB only functions in association with two other glycoproteins gH and gL which form a complex that regulate its activity. It is only when a fourth protein (gD for HSV-1 and gp42 for EBV) binds a cellular receptor, that the complex made by gH and gL undergoes a structural transition which itself triggers gB refolding.

Other Viral Fusion Glycoproteins

There are viral fusion proteins that cannot be classified in one of the three previously described classes.

Among unclassified fusion proteins from eukaryotic viruses are those of the genera pesti- and hepacivirus which both belong to the flaviviridae family. Unlike members of the flavivirus genus (which possess only one envelope glycoprotein, E), pestiviruses and hepaciviruses encode two envelope glycoproteins, E1 and E2. Based on the disulfide-bonds pattern, it was thought that the fusion protein was E2 and that it had a class II fold. However, structural studies performed on E2 of bovine viral diarrhea virus (BVDV, a pestivirus) and hepatitis C virus (HCV, a hepacivirus) revealed that neither BVDV E2 nor HCV E2 adopt a class II fold. Furthermore, BVDV E2 and HCV E2 structures, which otherwise are unrelated, appear to lack an N-terminal fusion peptide and internal fusion loops indicating that they are probably not viral fusion proteins. Finally, the structure of the amino terminal domain of HCV E1 reveals a complex network of covalently linked intertwined homodimers which definitively demonstrate that HCV has a novel fusion machinery of which the basic characteristics remain to be determined.

There are also many families of eukaryotic viruses for which little is known about the fusion machinery. As an example, the fusion machinery of poxviruses (of which the prototype is vaccinia virus) is not well characterized. Genetic and biochemical studies have provided evidence for an entry fusion complex, made up of about ten viral proteins, whose precise functions in the process are unknown. Similarly, the structure and working of the fusion machinery of the members of the Hepadnaviridae family (of which the prototype is Hepatitis B virus) is poorly understood.

Finally, in a very general manner, the fusion machineries of prokaryotic virus have not been characterized. A notable example is the determination of the fusion protein, called VP5, of two haloarchaeal pleomorphic viruses (HRPV-2 and HRPV-6) infecting archaeal hosts living in hypersaline environments and belonging to the Pleolipoviridae family. VP5 has a novel V-shaped fold and is monomeric on the viral surface. It may be a representative of a new class of prokaryotic virus fusion proteins.

Regulating the Conformational Change to Avoid Premature Triggering

As mentioned above, in most cases, the prefusion conformation of viral fusion proteins is metastable and the conformational change is irreversible. Therefore, premature triggering of the structural transition of the fusion protein is deleterious. This is particularly problematic for fusion glycoproteins that are triggered at low pH because, during their maturation and transport, they cross Golgi compartments that are slightly acidic. It appears that those viruses have evolved the ability to protect their fusion protein from undergoing irreversible transition toward their postfusion state and/or to avoid undesirable fusion reactions.

Some viruses have evolved the ability to regulate the pH of the transport vesicles. For influenza virus, this is achieved by the viral M2 protein which is a proton channel.

Furthermore, for all class I protein, the cleavage that primes the protein for the low pH-induced fusogenic conformational change occurs at a late stage of transport or even after viral budding in the extracellular medium.

Similarly, for class II fusion proteins, the cleavage of the companion protein is required to prime the fusion glycoprotein. The maturation process has been largely characterized for flaviviruses and particularly DENV. Immature DENV particles bud into the ER as spiky virions with 60 icosahedrally arranged protrusions, each consisting of a trimer of prM-E heterodimers. The immature particles are transported into the trans-Golgi network (TGN), where low pH environment induces a conformational change in the virion, resulting in a rearrangement of the surface glycoproteins and particles having a much smoother surface with E proteins arranged in the so-called herringbone pattern. This transition exposes the furin cleavage site allowing the proteolysis of prM into pr peptide and M to take place in the TGN. After cleavage, pr peptide remains associated with the virion. It stabilizes the metastable E dimer, preventing its dissociation and the formation of the postfusion homotrimers. It also masks the fusion loop of E, preventing interaction with host cell membranes. Finally, pr dissociates from the virion when the particle is released into the slightly alkaline extracellular medium. This definitively primes the metastable E dimer for subsequent low-pH-induced fusogenic conformational change.

For rhabdoviruses such as VSV or rabies virus, the native, prefusion conformation is not metastable and, as a consequence, the low-pH-induced structural transition is reversible. This allows G to be transported through the acidic compartment of the Golgi apparatus and to recover its native prefusion state at the viral surface in the extracellular environment.

Working of the Fusion Machinery

A Common Mechanism of Fusion

Experimental data suggest that the mechanisms for the catalysis of fusion are very similar for all the enveloped viruses studied so far whatever the organization of their fusion machinery.

Indeed, even though the structures of fusion proteins from the different classes are unrelated, the mechanisms for refolding share two key common features. First, the fusion peptides/loops are exposed and projected toward the viral membrane. Second, the folding-back of the C-terminal region onto a trimeric N-terminal region leads to the formation of a post-fusion protein conformation with the outer regions zipped up against the inner trimeric core. This refolding pathway constitutes the basis of the model presented for influenza HA in [Fig. 5](#).

Fig. 5 Schematic diagram of the fusion process between viral and cellular membranes mediated by influenza HA. In the prefusion conformation, the fusion peptide is buried in the trimer interface. Then, after release of HA1 subunits, the formation of a trimeric extended intermediate creates an initial bridge between the two bilayers. This extended intermediate is unstable and refolds into the more energetically favorable postfusion conformation. It is suggested that during this refolding stage the transmembrane domains are involved in the opening of the fusion pore. Similar schemes have been proposed for class II fusion glycoproteins.

Interaction With the Target Membrane

Interactions between fusion peptides and target membranes have been demonstrated for both rhabdoviruses and influenza virus using hydrophobic photolabeling. This interaction is an early step of the fusion process. This indicates that an early intermediate state during the structural transition exposes the fusion peptides that become accessible and are orientated toward the target membrane.

Polar aromatic residues (Tyr and Trp) located in the fusion loops of class II and class III fusion glycoproteins have been shown to be essential to the fusion process by directed mutagenesis experiments. They are supposed to position themselves at the interface between the fatty acid chains and the polar head group layers of lipids. For those glycoproteins, any deep penetration of the fusion domain inside the membrane is precluded by the presence of charged residues and polar groups close to the fusion loops. Such an interaction which only involves a few residues most probably perturbs the outer leaflet of the target bilayer and facilitates the formation of point-like protrusions that have been suggested to be stalk precursors.

Some class I fusion glycoproteins such as Ebov GP and ASLV Env also have fusion loops (located close to the amino-terminal end of the fusion subunit) which are enriched in aromatic residues. However, most class I fusion glycoproteins have a fusion peptide. Structures of synthetic fusion peptides of influenza virus HA2 and of HIV gp41 in membrane mimicking environments have been characterized by several biophysical approaches (including NMR and EPR spectroscopies) and molecular dynamics. In the case of HA2, the fusion peptide adopts a kinked helical amphipathic structure which, here again, does not seem to penetrate deep into the bilayer structure but rather induces local membrane curvature.

Structural Intermediates During the Conformational Changes

An elongated trimeric intermediate for class I and class II fusion glycoproteins

For class I fusion glycoproteins, it is assumed that the target-membrane-interacting conformation is in a trimeric extended conformation in which the central trimeric coiled-coil (made by HR1 heptad repeats) of the fusion subunit is already formed but the relocation of the C-terminal segments against this central core has not yet occurred. In this conformation, the fusion peptide is located at one end and interacts with the target membrane while the transmembrane domain, anchored in the viral membrane, is at the other end. This creates an initial bridge between the two bilayers.

Class II fusion glycoproteins form monomers during the structural transition. Although, here again, it is assumed that, at some stage, an extended trimeric intermediate is bridging the viral and target membranes, the oligomeric status of the glycoprotein when it interacts with the target membrane remains a matter of debate and may vary between class II glycoproteins. For TBEV E, the initial interaction with the target membrane seems to involve the insertion of multiple copies of E monomers. However, for SFV, it has been proposed that trimer formation is rapid and might precede membrane insertion.

For class I and class II fusion glycoproteins, the transition from the trimeric extended intermediate to the trimeric post-fusion state cannot maintain strict threefold symmetry. This symmetry is disrupted by the refolding -back of the C-terminal portion of the molecule. It is worth noting that during the structural transition from the putative intermediate to the post-fusion state, the TM segments cannot remain associated as they have to rotate independently of each other to achieve the transition.

Monomeric intermediates for vesiculovirus G

For VSV and Chandipura virus glycoprotein G, it has been demonstrated that both in solution (after proteolysis or detergent solubilization) and at the viral surface, there was an equilibrium between pre-fusion and post-fusion trimers and flexible monomers. The sequential appearance of the different species when lowering the pH suggested that the monomers were intermediates during the conformational change.

Two distinct intermediate monomeric conformations have been trapped in a single crystal form. The first one resembled the prefusion protomer and corresponded to an early intermediate. However, in this conformation, the partial refolding of the C-terminal segment of the ectodomain renders G able to bridge the viral and target membranes. The second one corresponded to a late intermediate on the transition pathway. Those two structures offer a plausible pathway for the conformational change and indicate that most of the structural transition occurs in a monomeric form and that retrimerization into the post-fusion state is a late event.

It is not clear whether this pathway can be generalized to other class III fusion glycoproteins. However, it is worth noting that independent refolding of G monomers before re-association to form the post-fusion trimer overcomes some of the problems encountered during class I and class II fusion glycoprotein refolding from their extended trimeric intermediate to their post-fusion state.

Cooperativity

Whatever the class of fusion glycoproteins, it has been shown that the fusion process requires the cooperation of several trimers. For influenza HA, West Nile Virus E and VSV G, the cooperation of 3–5 adjacent trimers is required to reach the hemifusion state. Cryo-electron tomography has suggested that they are organized around a lipid neck joining the viral and the liposome membranes.

It has also been suggested that glycoproteins located outside the contact zone might be involved in the late stages of the fusion process (i.e., the enlargement of the initial fusion pore). Indeed, several fusion glycoproteins in their post-fusion conformation have a tendency to cluster at the viral surface and sometimes form regular arrays. This is the case for several class II fusion glycoproteins of which spikes in their post-fusion conformation self-associate to form more or less regular networks that are different from the initial organization of the prefusion state. Similarly, VSV glycoproteins in their post-fusion conformation form helical arrays around the viral particle. The concerted formation of such networks might explain how glycoproteins surrounding the contact zone between fusing membranes exert a role at the late stages of the fusion process.

Conclusions

The structures of viral fusion glycoproteins and the deduced phylogeny illustrate nicely that viral genomes are a combination of gene modules that can be exchanged during evolution by horizontal transfer. Such transfers of genes could occur during co-infection of cells by distinct viruses. However, the homology between class II viral fusion glycoproteins and cellular fusogens suggest that viral fusion proteins genes may have been acquired from the genome of infected cells by viruses from unrelated viral families.

The field of virus fusion has greatly benefited from the progress of structural biology. This has revealed similar principles of action for fusion machineries made up of proteins having very different shapes. The next challenge is to determine how these fusion machineries operate when they interact with the target membrane and to get access to their dynamics at the highest possible spatial and temporal resolution.

Finally, viral fusion can constitute a target for antiviral strategies. several antiviral drugs that block enveloped virus fusion are already used or in development. A challenge for the future is to develop molecules that inhibit fusion machineries from a broad spectrum of viral families.

Glossary

Negative sense (–) strand A negative-sense DNA or RNA strand has a nucleotide sequence complementary to the messenger RNA and cannot be directly translated into protein.

Positive sense (+) strand A positive sense DNA or RNA strand has a nucleotide sequence, which is the same as that of the messenger RNA, and the RNA version of this sequence is directly translatable into protein.

Protein-primed DNA replication DNA replication whereby a DNA polymerase uses the 3'-OH group provided by the specialized protein as a primer to synthesize a new DNA strand.

RNA-primed DNA replication Conventional DNA replication used by all cellular organisms whereby a primase synthesizes a short RNA primer with a free 3'-OH group which is subsequently elongated by a DNA polymerase.

Rolling-circle DNA replication DNA replication whereby the replication initiation protein creates a nick in the circular double-stranded DNA and becomes covalently attached to the 5' end of the nicked strand. The free 3'-OH group at the nick site is then used by the DNA polymerase to synthesize the new strand.

Genomes of Prokaryotic Viruses

At present, all identified archaeal viruses have either double-stranded (ds) or single-stranded (ss) DNA genomes. Although metagenomic analyses suggested the existence of archaeal viruses with RNA genomes, this finding remains to be substantiated. Bacterial viruses, also referred to as bacteriophages or phages for short, have either DNA or RNA genomes, including circular ssDNA, circular or linear dsDNA, linear positive-sense (+)ssRNA or segmented dsRNA (Table 1). So far, no bacteriophages with negative sense (–)ssRNA genomes have been identified. Both archaeal and bacterial viruses with dsDNA genomes are most abundant, whereas those with ssDNA genomes represent a smaller group. The genome size of prokaryotic viruses is clearly linked with the structure of the genome. Thus, genomes approximately up to 25 kb in size are represented by both types of nucleic acids (DNA or RNA) and various topologies (circular, linear, segmented). All genomes larger than that are represented only by circular or linear dsDNA (Fig. 1). This size-dependent choice of the carrier of genomic information likely reflects physical constraints related to the genome stability, which is the highest for dsDNA.

Genome Replication of Prokaryotic dsDNA Viruses

Genomes of prokaryotic dsDNA viruses range from ~5 to ~500–600 kb, they can be either circular or linear. At present, dsDNA bacteriophages comprise the largest fraction of prokaryotic viruses that have their genomes sequenced. According to the data on complete viral genomes available at the NCBI database (see “Relevant Websites section”) currently the smallest dsDNA genome (10079 nt) of a bacterial virus is represented by the tailless *Pseudomonas* virus PM2. Phage PM2 is a representative of family *Corticoviridae* and the first lipid-containing phage to be isolated. The largest genome among officially classified bacterial dsDNA viruses belongs to the tailed *Bacillus* virus G (Order *Caudovirales*, Family *Myoviridae*) reaching nearly 500 kb (497513 nt). Recent metagenomics studies have identified phages with even larger dsDNA genomes that are in the 540–600 kb range. This points to the hidden diversity and abundance of very large phages and suggests that phages carrying even larger genomes might still be discovered. Notably, largest bacteriophage genomes are comparable in size with genomes of small bacteria capable of autonomous growth such as *Mycoplasma genitalium* with the 580 kb genome and exceed those of many symbiotic and parasitic bacteria. Archaeal dsDNA viruses range in size from 5.3 kb in the *Aeropyrum pernix* bacilliform virus 1 (APBV1), a member of the family *Clavaviridae*, to 144 kb for *Halogramma* tailed virus 1 (HGTV-1), a representative of the *Caudovirales*.

DNA replication has been studied in detail for only a handful of prokaryotic dsDNA viruses such as model bacteriophages phi29, T7 and T4. For most prokaryotic dsDNA viruses, however, there is little or no experimental data on their genome replication mechanisms. Therefore, whatever is inferred about DNA replication machineries for majority of prokaryotic dsDNA viruses typically comes from *in silico* analysis of viral genomes and corresponding proteomes. Based on both experimental characterization and computational analyses of the repertoire of putative DNA replication genes several major types of dsDNA genome replication systems can be distinguished. (1) A common type is the one that mirrors major molecular functions associated with RNA-primed DNA replication in cellular organisms. However, this type of DNA replication machineries may differ greatly in completeness in various prokaryotic viruses. Some, such as phage T4, have essentially autonomous DNA replication machinery, which does not require assistance from the host. Others encode only few components of their own and rely on the host to provide the remaining ones (e.g., phage lambda). (2) Protein-primed DNA replication system specific to viruses and other mobile genetic elements (MGEs). (3) Rolling circle DNA replication (RCR) system, in which the key component is a viral replication initiation protein

(Rep) whereas all or nearly all other proteins required for DNA replication are recruited from the host. (4) DNA replication systems that use other strategies to propagate viral genome (see below).

RNA-Primed DNA Replication

DNA replication systems in many prokaryotic viruses, particularly in bacteriophages, follow the same organizational principles as the corresponding systems of their cellular hosts. Archaea and bacteria use RNA-primed DNA replication systems that are made up of components which may not always be evolutionarily related, but perform the same function. At the most general level, cellular DNA replication machineries include the following key functional components: replicative helicases, primases, replicative DNA polymerases, DNA sliding clamps and clamp loaders, single-stranded DNA binding proteins, primer removal nucleases, DNA ligases and topoisomerases (Fig. 2). Typically, viral RNA-primed DNA replication machineries represent hybrid systems that are composed of proteins encoded by the viral genome and those provided by the host. According to the ratio of their own/host-provided DNA replication proteins viruses may differ considerably. Some viruses encode DNA replication systems that are essentially autonomous or nearly autonomous, whereas others encode only one or two DNA replication proteins and are largely dependent on the host to provide the rest. There is a continuum between these extreme cases. A global survey of viral-encoded DNA replication proteins has shown that both archaeal viruses and bacteriophages most frequently encode their own replicative helicases and not, as might be expected, DNA polymerases. Primases are also more frequent than DNA polymerases in both archaeal viruses and bacteriophages.

In addition, it was observed that certain functional categories of viral DNA replication proteins are tightly coupled. One such tightly coupled group comprises replicative helicase, primase and DNA polymerase. Viruses encoding either a DNA polymerase or primase nearly always encode a replicative helicase. The inverse co-occurrence is not nearly as stringent. Thus, in many cases, viruses, which encode replicative helicases, lack the genes for primases and DNA polymerases and likely rely on the corresponding proteins of the host. This asymmetry suggests that viral primases and DNA polymerases are constrained to work together with viral helicases. Such a coupling reflects intimate physical and functional interactions between these three proteins. Primase and helicase are often fused into a single polypeptide chain as exemplified by the primase-polymerase encoded by gene 4 of phage T7. There are

Fig. 1 Genome size ranges of prokaryotic viruses with different genome structure. B, bacteriophages, A, archaeal viruses. The inset shows a zoom-in on viruses with ssDNA and RNA genomes.

Fig. 2 Schematic representation of DNA replication fork based on bacteriophage T4 RNA-primed DNA replication system. The leading strand is synthesized continuously whereas the lagging strand is synthesized as Okazaki fragments. Newly synthesized strands are shown in magenta, RNA primers are represented as cyan-colored regions.

also cases where all three proteins (helicase, primase and polymerase) are fused together. One such example is the gp55 protein (Acc: YP_001828703) of *Lactococcus* phage 1706, and another one is the Pas55 protein (Acc: YP_024841) of *Actinoplanes* phage phiAsp2. Unfortunately, no experimental data are available on the molecular mechanism of these multifunctional proteins.

Another strong, unidirectional functional link was observed between viral DNA polymerases and their accessory factors, DNA sliding clamps and clamp loaders. It was found that all viruses which encode clamp loaders also encode DNA sliding clamps and DNA polymerases. This co-occurrence pattern is a direct reflection of steps involved in the assembly of a processive DNA replicase. The clamp loader loads the clamp, which in turn tethers DNA polymerase to the DNA enabling processive DNA synthesis. Again, the opposite link between the presence of a viral polymerase and accessory proteins is weak. The reason for this is that some viral DNA polymerases have high intrinsic processivity whereas others utilize host proteins to increase the processivity of DNA synthesis. A well-known example of host-supplied processivity factor is the case of *Escherichia coli* phage T7. By itself the T7 DNA polymerase is a low-processivity enzyme, however, upon binding the *E. coli* thioredoxin the processivity of the DNA polymerase increases by about 1000-fold.

Note: DNA replication proteins are marked by their presence in the genome (present, black square; absent, white square; present in some members, black-and-white square). Viruses are arranged by the genome size and colored by their host (yellow, bacteriophages; pink, archaeal viruses). Adapted from Kazlauskas, D., Krupovic, M., Venclovas, Č., 2016. The logic of DNA replication in double-stranded DNA viruses: Insights from global analysis of viral genomes. *Nucleic Acids Research* 44, 4551–4564.

What determines the completeness of the viral genome-encoded DNA replication machinery? It appears that one of the key factors is the size of the viral genome. In a sense, viral genome may be compared to a computer disk – the larger the disk, the more data it can hold (Fig. 3). For example, both archaeal and bacterial viruses with dsDNA genomes exceeding 140 kb all encode their own replicative helicases and DNA polymerases. However, the correlation between the genome size and the completeness of the viral-encoded DNA replication machinery is quite noisy and far from perfect. The increased coding capacity of viral genome is not always a decisive factor. This can be clearly seen in the list of prokaryotic viruses with the most complete DNA replication machineries (Table 2). For example, phage T4 with the 169 kb genome has all the components needed for the genome replication, whereas a phage with the 498 kb genome (*Bacillus* phage G) lacks the recognizable accessory subunits (DNA sliding clamp and clamp loader) of a DNA polymerase.

Not only the completeness of viral DNA replication machineries is highly variable, but also components making up these machineries are highly diverse. In particular, DNA replication proteins used by bacteriophages often differ from those used by their bacterial hosts. For chromosomal DNA replication bacteria use the DnaB-type superfamily 4 (SF4) helicases, TOPRIM domain-containing primase (i.e., *E. coli* DnaG), C-family DNA polymerase, processivity β -clamp and bacterial clamp loader, OB-fold-containing SSB protein. RNA primers in bacteria are excised by RNase HI and Pol I 5'-3' exonuclease domain homologous to FEN1. Nicks are then sealed by a NAD⁺ – dependent DNA ligase. DNA replication machineries encoded by bacteriophages represent a mosaic of proteins typical of bacterial hosts, proteins of archaeo-eukaryotic type and those specific to viruses and other MGEs. Thus, bacteriophages are not simply mirroring DNA replication systems employed by their bacterial hosts. There are a number of components notably different from the bacterial ones. Among these are Superfamily 3 (SF3) helicases that are specific to MGEs and that are not involved in chromosomal replication of cellular organisms. Bacteriophages also frequently encode archaeo-eukaryotic primases (AEP) that have unrelated structural fold to bacterial TOPRIM primases. Most interestingly, C-family DNA polymerases that represent replicative polymerases in bacteria, are rarely found in bacteriophages. Instead, most abundant DNA polymerases in bacteriophages are represented by A- and B-family enzymes, both featuring the same structural fold of their catalytic domain. A-family polymerases in bacteria are ubiquitous, but their role is limited to participation in gap-filling during replication and in DNA repair. B-family polymerases in eukaryotes and archaea represent replicative enzymes whereas in bacteria their presence is sporadic. Thus, B-family polymerases provide another link between bacteriophage and archaeal/eukaryotic replication machineries. Some bacteriophages have DNA polymerase accessory proteins that also appear to be of archaeal/eukaryotic origin. The case in point is DNA sliding clamps and clamp loaders of T4-like bacteriophages. Both archaeal/eukaryotic (PCNA) and T4 (gp45) clamps are homotrimers, unlike the dimeric bacterial β -clamps. In addition, the crystal structure of T4 clamp loader (gp44/62) revealed that it represents a minimal version of the archaeal/eukaryotic RFC clamp loader. Archaeal/eukaryotic proteins participating in the lagging strand synthesis, most notably ATP-dependent DNA ligase, are also common in bacteriophage genomes.

Components of DNA replication systems encoded by archaeal viruses generally are homologous with the archaeal counterparts. However, there are fewer complete genomes of archaeal viruses, they tend to be smaller than in the case of bacteriophages and they are extremely diverse. Therefore, it is difficult just yet to make broader generalizations regarding components of RNA-primed replication systems in archaeal dsDNA viruses. Notably, some previous analyzes of complete archaeal genomes failed to find typical SSB proteins featuring OB-fold. However, a more recent metagenomics study identified archaeal members of the *Caudovirales*, dubbed Magroviruses, that possess dsDNA genomes of 65–100 kb in size and encode a nearly complete replication apparatus of apparent archaeal origin including SSB proteins. In addition to typical archaeal/eukaryotic proteins, just like bacteriophages, archaeal viruses were found to encode SF3 helicases, specific to MGEs.

Thus, there are some DNA replication proteins of prokaryotic viruses that are spread across both bacterial and archaeal domains. The 'universal' proteins include SF3 helicases, AEP primases, B-family DNA polymerases, RNase H and ATP-dependent DNA ligases. Only RNase H is commonly found in both bacteria and archaea, the remaining proteins, except SF3 helicases, are of archaeal/eukaryotic origin. If the similarity is considered at the structure level, the set of common archaeal/eukaryotic proteins could be extended even further into DNA sliding clamps and clamp loaders (PCNA/T4 gp45 and RFC/(T4 gp44/gp62)).

Protein-Primed DNA Replication

Some bacterial viruses with relatively small linear dsDNA genomes utilize the so-called protein-primed DNA replication. Cellular replicases use the 3'-hydroxyl (3'-OH) group provided by a nucleic acid primer (RNA or DNA) to initiate DNA synthesis. In contrast, protein-primed DNA polymerases utilize the OH group presented by a specific serine, threonine or tyrosine residue of a terminal protein (TP). Protein-primed DNA replication systems are distinctly different from those utilizing nucleic acid primers. Unlike the latter, protein-primed DNA replication systems require only few components to be fully functional. Such systems typically include a distinct B-family DNA polymerase, TP and an atypical single-stranded DNA binding protein (SSB). The DNA replication machinery of a protein-primed DNA replication system may be exemplified by one of the best studied such systems from *Bacillus subtilis* phage phi29 (Fig. 4). Phage phi29 genome is a linear approximately 19 kb-long dsDNA with covalently attached TP to each 5'-end. DNA replication is initiated by binding of the heterodimer of phi29 DNA polymerase and the free TP to the genomic DNA ends. Phi29 DNA polymerase uses the OH group of a specific serine residue as a primer bypassing the need for a primase. During the extension stage the phi29 DNA polymerase continues to synthesize DNA in a standard DNA-primed fashion and the displaced single-stranded regions are covered by SSB. Once the replication of a single DNA duplex is completed, there are two newly synthesized linear DNA duplexes with TP covalently attached to the 5'-ends. The structure of the phi29 DNA polymerase, so far the only experimentally determined 3D structure of a protein-primed DNA polymerase, has been instrumental in understanding structural and functional features of protein-primed DNA polymerases. Phi29 and other protein-primed DNA polymerases have two additional subdomains, Terminal Protein Region 1 (TPR1) and 2 (TPR2), that distinguish them from B-family members involved in conventional RNA-primed DNA replication. The TPR1 subdomain is involved in interaction with the TP. The palm, thumb and TPR2 subdomains form an internal sliding clamp-like structure that encircles the upstream duplex DNA, providing the enzyme with its inherently high processivity without the assistance of processivity factors. In addition, the TPR2 subdomain of the phi29 DNA polymerase couples processive DNA synthesis with the strand displacement in downstream dsDNA, making the function of a replicative helicase unnecessary. Based on identified genes for protein-primed DNA polymerase,

Fig. 4 Schematic representation of protein-primed replication of bacteriophage phi29. Pol, polymerase; TP, terminal protein; SSB, single-stranded DNA binding protein. Newly synthesized strands are shown in magenta.

five groups of archaeal viruses are also believed to replicate their genomes in this manner. These groups include bottle-shaped ampullaviruses, spindle-shaped salterprovirus His1, pleolipovirus His2, *Sulfolobus ellipsoid virus 1* and *Methanosarcina* Spherical Virus (MetSV). However, in these cases protein-primed DNA replication systems have not been studied experimentally. Apparently, the protein-primed DNA replication system is optimal for small-sized viral genomes, because these systems have only been identified in viruses with dsDNA genomes of no more than 50 kb.

Rolling Circle DNA Replication

Some archaeal and bacterial dsDNA viruses lacking typical components of either RNA-primed or protein-primed DNA replication systems utilize the so-called rolling circle DNA replication (RCR) mode. The signature of RCR is the presence of the multifunctional replication initiation protein (RCR-Rep). In many cases, RCR-Rep is the only viral protein needed for viral DNA replication. Therefore, RCR replication systems are prevalent in small viral genomes. The RCR replication mode is not specific to dsDNA prokaryotic viruses. In fact, RCR was first discovered and characterized in *E. coli* bacteriophage phiX174 and other ssDNA bacteriophages. Subsequently, RCR was identified as the replication mode of many other genetic elements such as bacterial and archaeal plasmids as well as a mechanism used by plasmids for conjugative DNA transfer. DsDNA bacteriophages that utilize the RCR replication mode include bacteriophages such as P2, 186, HP1 and PM2. The general mechanism of dsDNA bacteriophage genome replication using the RCR mode can be illustrated with that of bacteriophage P2 (**Fig. 5**). Following the entry of linear P2 DNA into the host cell, DNA circularizes due to the cohesive DNA ends and is sealed by the cellular DNA ligase. The RCR-Rep protein (protein A) of bacteriophage P2 nicks a circular DNA at the replication origin generating the covalent protein-DNA intermediate and a free 3'-OH. The latter primes leading strand DNA synthesis by the bacterial replicase, which uses the non-cleaved strand as a template. After the full circle is replicated, protein A cuts the newly generated origin and also acts as a ligase, producing a covalently closed circular ssDNA molecule. In this way, RCR-Rep is able to perform multiple rounds of cleavage and ligation at the origin by what has been termed a "flip-flop" mechanism. The circular ssDNA is converted to dsDNA by the replication machinery of the host.

Some archaeal dsDNA viruses are also known to encode RCR-Rep homologs. Among those archaeal viruses are rudiviruses that all have a candidate RCR-Rep protein. The structure of the RCR-Rep protein (gp119) of *Sulfolobus islandicus* rod-shaped virus 1 (SIRV1) has been solved and it revealed similarity to the HUH endonuclease superfamily. DNA replication of another rudivirus, SIRV2, has been studied experimentally. These studies revealed that although SIRV2 RCR-Rep protein can both nick and seal DNA like canonical RCR-Rep proteins, the RCR replication mode cannot fully explain the experimental observations. Based on the observed multimeric and highly branched DNA replication intermediates, it was suggested that SIRV2 could employ a combination of strand-displacement, rolling-circle and strand-coupled genome replication mechanisms. Whether all of these mechanisms occur during each cycle of viral DNA replication remains unclear. In another archaeal virus, sphaerolipovirus SNJ1 (*Sphaerolipoviridae*), the RCR-Rep protein of the HUH endonuclease superfamily has been experimentally shown to be essential for

Fig. 5 Schematic illustration of the rolling-circle DNA replication based on the bacteriophage P2 replication mechanism. Phage RCR-Rep protein cuts the circular dsDNA at the replication origin (cyan) generating the covalent protein-DNA intermediate and a free 3'-OH group. Host's replicase utilizes the 3'-OH group as a primer and synthesizes the new (+) strand (magenta) while displacing the original strand. After the full circle is replicated, RCR-Rep nicks the newly generated origin at the same time sealing the displaced strand to produce a closed ssDNA circle. Host's replication machinery converts circular ssDNA to dsDNA by synthesizing complementary (-) strand (magenta). In the case of ssDNA viruses replicating through RCR, the latter process is the initial step in DNA replication.

viral genome replication. Furthermore, point mutations confirmed that the inferred catalytic residues of RCR-Rep are essential for its functionality. As pointed out above, the RCR mode of replication can be used by either dsDNA or ssDNA genomes. This is nicely illustrated in the case of haloarchaeal pleomorphic viruses. For example, *Haloarcula hispanica* pleomorphic virus 1 (HHPV-1) with circular dsDNA genome is closely related to *Halorubrum* pleomorphic virus 1 (HRPV-1) with circular ssDNA genome and both encode a homolog of RCR-Rep protein.

Since RCR is not the main replication mode in dsDNA prokaryotic viruses, but is prevalent in ssDNA viruses, the detailed discussion on the RCR mechanism and RCR-Rep proteins is provided in the section devoted to the replication of ssDNA viruses (see below).

Other DNA Replication Mechanisms

There are prokaryotic dsDNA viruses lacking any of the components indicative of a specific DNA replication system such as a replicative helicase (suggestive of RNA-primed DNA replication), a protein-primed DNA polymerase (protein-primed DNA replication) or an RCR-Rep homolog (suggestive of the RCR replication mode). In such cases dsDNA bacteriophages frequently encode either integrases, DNA recombination proteins or various replication initiation proteins, including homologs of bacterial replisome organizer DnaA and helicase loader DnaC. These observations suggest that in these cases viral genome is either

integrated into the host genome and propagated by the replication of the host genome or other proteins in the replication initiation stage are used to recruit cellular replication proteins. There are also cases when no typical DNA replication proteins were detected in the viral genomes. In particular this is true in the case of archaeal viruses. These viruses might either have highly diverged DNA replication proteins that cannot be detected by current computational approaches or use new replication strategies. The existence of the latter possibility is exemplified by *Acidianus* filamentous virus 1 (AFV1), which appears to use a novel strand displacement mechanism.

Genome Replication of Prokaryotic ssDNA Viruses

Viruses with ssDNA genomes are among the smallest viruses and encode as few as two proteins – one for capsid formation and the other one for genome replication. ssDNA bacteriophages have circular genomes and are classified into two families, *Microviridae* and *Inoviridae*. The *Microviridae* family comprises ssDNA phages with small icosahedral capsids including archetypal phage phiX174. Members of this family have circular ssDNA genomes in the 4.4–6.1 kb range. The *Inoviridae* family comprises filamentous ssDNA phages such as the M13 phage. Inoviruses also have circular ssDNA genomes and their size is in the 4.5–12.4 kb range. Officially recognized ssDNA bacteriophages represent only a small fraction in comparison with dsDNA bacteriophages. However, recent metagenomic studies found that ssDNA bacteriophages are present in various environments and that their abundance and diversity have been underestimated.

Archaeal viruses that have ssDNA genomes belong to two officially recognized families, *Pleolipoviridae* and *Spiraviridae*. Members of *Pleolipoviridae* similarly to the ssDNA bacteriophages have rather small ssDNA genomes ranging from 7 to 10.6 kb. Strikingly, the family *Pleolipoviridae* comprises viruses not only with ssDNA genomes, but also with either linear or circular dsDNA genomes. This observation complicates the traditional virus classification based on genome type. Not all archaeal ssDNA viruses are small. The sole member of the *Spiraviridae* family, *Aeropyrum* coil-shaped virus (ACV) infecting an extreme aerobic hyperthermophile (*A. pernix*) was found to have an unusually large (24.9 kb) ssDNA genome. So far, the ssDNA genome of ACV is the largest among all known ssDNA viruses.

Rolling Circle Replication

Most bacteriophages possessing ssDNA genome replicate using the RCR mechanism. In general, genome replication of ssDNA bacteriophages is similar to the RCR-using dsDNA viruses (see Fig. 5). The key difference is that in the case of ssDNA phages there is an additional stage, the conversion of ssDNA into dsDNA. The whole process can be generally divided into three stages as exemplified by the phage phiX174 replication. During the first stage, the infecting (+)ssDNA is converted by host replication proteins into a covalently closed dsDNA called replicative form DNA (RF). During the second stage, RF DNA is amplified. RCR-Rep (protein gpA) nicks the DNA at the origin of replication forming the covalent 5'-phosphotyrosine intermediate and a free 3'-OH. The 3'-OH serves as a primer for host DNA replicase which uses (–) strand as a template to synthesize DNA by “peeling off” the (+) strand. After one round of rolling circle synthesis, RCR-Rep cuts the newly generated origin and acts as a ligase, producing a covalently closed circular (+)ssDNA molecule. Newly generated (+)ssDNA genomes are again converted into dsDNA circular molecules. During the last stage of DNA synthesis, the ssDNA genome is concurrently synthesized and packaged into the viral procapsid.

The key role in ssDNA replication belongs to a multifunctional RCR-Rep protein. Early on it was noticed that RCR-Rep proteins are not monophyletic and that they often cluster with corresponding proteins from rolling-circle plasmids found in bacteria and archaea. Bacteriophages with ssDNA that replicate through the RCR mechanism use RCR-Rep proteins belonging to at least two evolutionarily and structurally distinct superfamilies, the HUH endonucleases and the TATA-box binding protein-like enzymes.

The superfamily of HUH endonucleases is named after the conserved metal binding HUH motif, consisting of two His residues separated by a bulky hydrophobic residue (U). In addition, HUH endonucleases have either one or two catalytic Tyr residues that form the covalent 5'-phosphotyrosine intermediate during nicking of ssDNA. The phage phiX174 RCR-Rep (protein gpA) represents the founding member of the RCR-Rep HUH endonucleases. It uses two catalytic Tyr residues to initiate and terminate rolling-circle replication and to spin off multiple circles of phiX174 ssDNA. Remarkably, despite decades of studies the structure of phiX174 gpA, the founding member of HUH endonuclease superfamily, remains unsolved. Peculiarly, the closest homolog with the solved three-dimensional structure appears to be a protein (PDB id: 2X3G) from dsDNA archaeal virus SIRV1. HUH endonucleases have the ferredoxin-like fold which is also known as the RNA recognition motif (RRM). HUH endonucleases also share similarity with origin binding proteins of small dsDNA viruses suggesting that there are intricate and ancient evolutionary relationships between these proteins.

RCR-Rep proteins of the second class, typified by GP2 of phage M13, belong to the Pfam family *Phage_CRI* (PF05144) and the related *Rep_trans* (PF02486) family of plasmid replication initiation proteins. Only recently the first three-dimensional structures of *Rep_trans* family members have been solved. These structures revealed that RCR-Rep proteins of *Rep_trans* family feature TATA-box binding protein-like (TBP-like) structural fold, which is entirely different from the RRM fold of HUH endonucleases. The metal binding site is also organized differently. *Rep_trans* representatives do not have the HUH motif. Instead, the metal binding is mediated by three acidic residues. However, despite structural differences and differently organized metal binding sites of the two types of RCR-Rep proteins, both types use an active site tyrosine residue as the nucleophile during the nicking/religation reactions. Moreover, the side chains of the corresponding catalytic tyrosine residues adopt a similar orientation with respect to the metal ions.

Therefore, these two different types of RCR-Rep proteins may represent a case of convergent evolution for catalyzing the same nicking and religation reactions. Interestingly, even within the same phage family RCR-Rep proteins may be of different types as exemplified by *Inoviridae*. Thus, the RCR-Rep protein from *Xanthomonas* phage Lf is a member of the HUH endonuclease superfamily, whereas the one from phage M13 belongs to the TBP-like superfamily.

Most ssDNA archaeal viruses, similarly to ssDNA bacteriophages, likely replicate their genomes via RCR or related rolling hairpin replication mechanisms as implied by the identified RCR-Rep homologs. A candidate replication initiator (Rep) family gene was identified in HRPV-1, a representative of the *Pleolipoviridae* family and the first characterized archaeal virus having ssDNA genome. The HRPV-1 Rep gene is homologous to RCR-Rep HUH endonucleases. On the other hand, no potential candidate showing significant sequence homology or sharing conserved motifs with known RCR-Rep proteins could be identified in ACV, a virus with the largest ssDNA genome, suggesting that it might use a unique mechanism of genome replication.

Genome Replication of Prokaryotic RNA Viruses

RNA viruses are divided into three distinct classes depending on the nature of their genome: positive-sense (+) single-stranded RNA (ssRNA) viruses, double-stranded (ds) RNA viruses, and negative-sense (–) ssRNA viruses. Although RNA viruses infecting eukaryotes are very common, the known representation of prokaryotic RNA viruses is quite narrow. Currently, there are only two recognized families of RNA bacteriophages, the *Leviviridae* family consisting of (+)ssRNA bacteriophages and the *Cystoviridae* family comprising segmented dsRNA bacteriophages. So far, no (–)ssRNA bacteriophages have been isolated. At present, there are no known RNA viruses that infect archaea. Although the putative presence of archaeal (+)ssRNA viruses has been reported, this finding remains unsubstantiated. Recent metagenomics surveys in diverse environments have substantially expanded known host range and spectrum of genome architectures of RNA bacteriophages. Nonetheless, it appears that the prokaryotic RNA virome is both significantly smaller and less diverse than the DNA virome.

The *Leviviridae* family comprises bacteriophages with (+)ssRNA genomes. The family includes four recognized species (Enterobacteria phage Q β , Enterobacteria phage F1, Enterobacteria phage MS2, and Enterobacteria phage BZ13). Bacteriophages of the *Leviviridae* family have a monopartite (+)ssRNA genome of 3.3–4.3 kb in size and are among the simplest and smallest of known viruses. Notably, the genome of phage MS2 was the first ever genome to be fully sequenced.

The *Cystoviridae* family for over two decades was represented by only one recognized virus species, *Pseudomonas* phage ϕ i6. Recently, a number of additional dsRNA phages have been isolated from various environmental samples and six of them (*Pseudomonas* phages ϕ i8, ϕ i12, ϕ i13, ϕ i2954, ϕ iNN and ϕ iYY) have been fully sequenced. All seven ICTV-recognized species of the *Cystoviridae* family have a dsRNA genome, which is divided into three separate segments: large (L), medium (M) and small (S). Individual segments range in size from 2.9 to 6.4 kb. The total genome size varies from 12.7 kb (ϕ i2954) to 15.0 kb (ϕ i8).

Replication Using an RNA-Dependent RNA Polymerase

Bacterial hosts lack the capability to synthesize complementary strands using the RNA strand as a template. Thus, all characterized RNA phages encode their own RNA-dependent RNA polymerase (RdRp). Notably, RdRp is the only universal protein not only in RNA phages, but in all known RNA viruses. In (+)ssRNA phages, the genome serves simultaneously as a genome template and as messenger RNA (mRNA). Since replication and translation run in the opposite directions, there is a competition between the two processes. Viral RdRp assembles with host proteins (ribosomal protein S1, translation elongation factors EF-Tu and EF-Ts) to form the active RNA polymerase holoenzyme (replicase). The replicase then initiates synthesis of the negative RNA strand by replicating through the (+)ssRNA genome. In turn, the newly synthesized (–)ssRNA strand is used to produce new (+)ssRNA genomes for the viral progeny.

In the case of dsRNA phages, RdRp (P2) is encoded in the largest genome fragment. The cystoviral RdRp first initiates synthesis of the plus-strands by unwinding each of the dsRNA segments and using the minus-strands as template. Newly synthesized (+)ssRNA segments (+S, +M, +L) are utilized as mRNAs by the host translational machinery. Once phage proteins are produced, the empty procapsids are self-assembled and the three (+)ssRNA segments are packaged into each of them. Following packaging, P2 initiates a single round of minus-strand RNA synthesis to recapitulate the dsRNA phage genome.

RdRps of (+)ssRNA and dsRNA phages as well as those of eukaryotic RNA viruses are evolutionary related. Viral RdRps belong to the class of right-hand polymerases that share the same RRM structural fold of their “palm” domain. This class also includes single-subunit DNA-dependent RNA polymerases, reverse transcriptases and DNA polymerases of A, B and Y families. Based on both sequence and structure analysis it was suggested that RdRps may represent the most ancient group of right-hand polymerases in agreement with the RNA World hypothesis, because RdRps could serve as replicases of RNA genomes. Phylogenetic analyses have further suggested that RdRps of dsRNA viruses evolved from (+)ssRNA viruses pointing to their ancient origin.

Concluding Remarks

Genome replication strategies employed by prokaryotic viruses are extremely diverse. This diversity in part can be explained by differences in type (DNA or RNA) and topology (linear or circular, double- or single-stranded, contiguous or segmented) of nucleic

acids encoding viral genomic information. However, even those prokaryotic viruses that, like cellular organisms, have dsDNA genomes, show remarkable diversity both in replication strategies and in composition of their DNA replication machineries. Interestingly, bacterial viruses often encode DNA replication proteins typical not of bacteria, but of archaea and eukaryotes, pointing to an ancient and complex evolutionary history of dsDNA replication systems of bacteriophages. Other viral DNA replication strategies such as protein-primed DNA replication and rolling circle replication evolved within a broader context of mobile genetic elements and apparently also have deep roots. Viral RNA-dependent RNA polymerases are believed to represent the most ancient group of right-handed polymerases in accord with the RNA world theory. Therefore, studies of viral proteins involved in genome replication might hold important clues for the emergence and the evolution not only of viral but also of cellular DNA replication machineries. A very fast pace at which genomic and metagenomic data for viruses are currently accumulating provides a solid basis for such studies.

Viral Transcription

David LV Bauer, Francis Crick Institute, London, United Kingdom

Introduction

While viruses vary in their genome organization and genetic makeup, they all face the same fundamental task of producing a mRNA that is recognized by the host ribosome and translated to produce viral proteins. This process – viral transcription – varies depending on the virus family and lifecycle, though a number of general principles are common to nearly every virus. In the case of RNA viruses, transcription requires a virus-encoded enzyme, RNA-directed RNA polymerase (RdRp) that can use RNA, rather than DNA, as a template for mRNA synthesis.

General Principles of Viral Transcription

Degree of Dependence on Host Transcription Machinery

Two factors determine the extent to which viruses may rely on host machinery for transcription: their genome type (DNA vs. RNA) and, for viruses that infect eukaryotic hosts, the cellular compartment in which the viral genome is transcribed. DNA viruses that transcribe in the nucleus (e.g., most DNA viruses and reverse transcribing RNA viruses in their DNA provirus stage) can effectively mimic the host genome and utilize the host transcription machinery fully – including RNA Polymerase II (Pol II), which is the DNA-dependent RNA polymerase responsible for mRNA transcription in eukaryotes (Fig. 1(A)). DNA viruses that transcribe their genome in the cytoplasm (e.g., poxviruses) must encode their own RNA polymerase. In contrast, RNA viruses cannot rely on host Pol II, since Pol II is unable to use their RNA genomes as a template for transcription. Instead, all RNA viruses encode an RNA-dependent RNA polymerase (RdRp), which is used for both genome replication and transcription (Fig. 1(B)). RNA viruses that replicate in the nucleus, however, may still exploit other aspects of host RNA processing.

Features of Viral Transcripts at the 5' and 3' Ends Promote Translation

In eukaryotes, translation of mRNA is typically dependent on the presence of a 5'-cap and a 3' poly(A) tail. Viruses that depend on host Pol II for transcription (e.g., nuclear-transcribing DNA viruses) follow the canonical pathway to generate these structures: the 5'-cap is added by the host capping machinery following transcription initiation by Pol II, and the poly(A) tail is added by poly(A) polymerase following recognition of a poly(A) signal and cleavage of the nascent transcript by the host cleavage and polyadenylation specificity factor (CPSF).

Fig. 1 Mechanisms of viral transcription in eukaryotic viruses that transcribe (A) from a dsDNA template, or (B) from a RNA template, as discussed in this text. Open reading frames (ORF) are represented as solid-filled shapes.

A broad range of viruses that do not depend on host Pol II, including cytoplasmic-transcribing DNA viruses (e.g., poxviruses) and the majority of RNA viruses, have adopted the strategy of effectively generating this canonical RNA structure on their own. Such a strategy involves either encoding enzymes to synthesize a 5'-cap *de novo*, or enzymes to cleave host mRNAs at their 5' ends in order to "snatch" 5'-caps for use in viral transcripts. Similarly, such viruses may generate a poly(A) tail by encoding their own poly(A) polymerase, by transcribing directly from a long poly(U) tract, or by stimulating the viral RdRp to "stutter" and repeatedly add non-templated A bases to the nascent RNA transcript.

RNA viruses that neither depend on host Pol II, nor encode their own capping or cap-snatching machinery, have adopted an alternate strategy in which the function of the canonical 5'-cap and 3' poly(A) tail are supplanted by virus-specific elements.

In the canonical host mRNA pathway, mRNA is exported from the nucleus and translation initiation is driven by recognition of the 5' cap by eukaryotic initiation factor (eIF) 4E, leading to assembly of the eukaryotic initiation complex and the ribosome upstream of the translation start codon. Some ssRNA(+) viruses contain a highly structured RNA motif at their 5' end of their genome, which acts to recruit the ribosome independently of a 5' cap. This RNA motif, termed an internal ribosome entry site (IRES), may interact with the eIF complex or the ribosomal subunits directly in order to drive translation of the viral RNA. Additionally, some ssRNA(+) viruses covalently link a viral protein to the 5' end of their genome (Viral Protein genome, VPg). While the VPg protein serves to protect the 5' end from degradation and to prime RNA synthesis by the RdRp, in some viruses (e.g., astroviruses and caliciviruses), it interacts directly with the eIF complex to promote translation.

The 3' end of mRNA also facilitates translation. In canonical translation of mRNA, the poly(A) tail is bound by poly(A) binding protein (PABP), which in turn binds the eIF complex that is bound to the 5'-cap of the same mRNA. The resulting circularization of RNA facilitates translation by promoting ribosome "recycling" following each round of translation. Some RNA viruses (e.g., flaviviruses) lack a poly(A) tail, but promote this process by encoding 3' RNA structures that bind PABP directly and also contain sequence complementary to the 5' region that promotes base-pairing between the two ends of the genome – though it is not clear whether these promote translation or, rather, replication by the RdRp. Some RNA viruses (most notably those that infect plants), contain a tRNA-like structure in their 3' untranslated region (UTR) that can be aminoacylated, promoting both RNA stability and translation. More broadly, the 3' UTR of mRNAs contain sequence elements that determine their stability, which are also exploited by viral RNAs.

Transcription Strategies Determine Mechanisms of Host Shutoff

Most viruses have adopted strategies to repress host gene transcription and translation, broadly termed "host shutoff", which serve to both conserve cellular resources for viral functions, and to prevent the host from expressing antiviral genes. The mechanisms of host shutoff that are available to a virus are determined by the degree to which it is dependent on host transcription. For example, viruses that generate transcripts with canonical host mRNA structures at their 5' and 3' end do not broadly inhibit canonical translation mechanisms – whereas viruses without these structures may target the components of the eIF complex or PABP. Similarly, viruses that do not rely on host transcription machinery, for example, may inhibit Pol II directly, or broadly target RNA splicing, 3' end processing, or mRNA export. Host shutoff does not have to be a binary process: specific viruses that use components of these pathways may modulate them so as to enhance their function, while also encoding mechanisms to block unused aspects of these pathways.

Overall Genome Organization Orchestrates Viral Transcriptional Program

Viral transcription takes place in the context of the lifecycle of a given virus: genes necessary early in infection are not necessarily needed late in infection – and vice versa. Viral genomes are therefore often arranged so that the order of transcription matches the temporal requirements for gene expression. This fundamental feature was first observed in bacteriophages, and is a common feature of many viruses that divide their genes approximately into those expressed early, middle, and late in infection. Broadly speaking, early genes are associated with establishing infection and suppressing host antiviral responses; middle genes are associated with genome replication or establishing latency; and late genes are associated with the production of the structural components of new virions.

Such transcriptional patterns can be achieved by diverse mechanisms: DNA viruses may encode motifs that are recognized by existing cellular transcription factors to activate or repress a given gene under certain conditions – or encode their own – to generate a transcriptional cascade. Similarly, they may also control the use of alternate splice or alternate poly(A) sites through the expression of viral proteins that change downstream expression as infection progresses. RNA viruses that exploit host RNA splicing factors may do the same. Some DNA viruses also encode their own viral DNA-dependent RNA polymerase in order to control the transcription of middle- and late-stage viral genes while removing their dependence on the host RNA polymerase – a notable feature of bacteriophage T7, for example.

RNA viruses follow a similar pattern, often arranging their genomes so that genes needed early in infection are transcribed (and translated) first. This arrangement, common in ssRNA(–) viruses, allows control of transcript abundance by regulating the proportion of RdRps that continue to transcribe from one block to another. This arrangement is also present to a certain extent in simple ssRNA(+) viruses for which viral genome transcription and replication are not differentiated: these viruses may produce a polyprotein that is cleaved into N-terminal proteins that are more typical of "early" genes and C-terminal proteins more typical of "middle" and "late" genes, though the relative levels of each protein cannot be controlled transcriptionally.

More complex ssRNA(+) viruses (e.g., coronaviruses) separate their “late” genes encoding viral structural proteins at the 3′ end of the viral genome, and require transcription by the viral RdRp to produce subgenomic RNA (sgRNA), directed by specific RNA motifs. Segmented RNA viruses follow a more complex pattern, often using RNA structures to control the level of transcription of each segment – indeed, the exploitation of the ability of RNA to form complex secondary and tertiary structures is exploited by nearly all RNA viruses to modulate the activity of the RdRp.

RNA Viruses Encode a RdRp that Transcribes and Replicates Their Genome

While DNA viruses may take advantage of existing host polymerases to replicate and transcribe their genes, RNA viruses must encode their own replicase and transcriptase since host cells do not encode enzymes that can generally use RNA as a template for RNA synthesis – i.e., they lack RNA-directed RNA polymerases (RdRps).

The simplest RNA viruses, such as picorna- and flaviviruses, take the form of an infectious mRNA that encodes the necessary proteins to replicate and transmit its genomic material from an infected cell to a new host cell. In these viruses, the function of the RdRp is to replicate the viral genome, and there is no distinct “transcription” step. As discussed above, specialization of RNA synthesis for mRNA production vs. genome replication permits control over protein levels at the level of transcripts.

While more complex ssRNA(+) viruses carry out transcription to generate sgRNAs, transcription is still not required to express genes at the 5′ end of the genome. In contrast, all dsRNA and ssRNA(−) viruses must first carry out a distinct transcription step to generate (+)-sense RNA that is translated into viral proteins. As a result, RdRps are packaged into virions in order to initiate transcription (and thus infection) in new host cells. In all cases, the RdRp must also be able to shift between transcription and replication activities, which are often mechanistically distinct.

RdRps Contain an Evolutionarily Conserved Architecture

All viral RdRps share common structural motifs that are characteristic of template-dependent nucleic acid polymerases, including an overall domain architecture that resembles a cupped right hand, composed of a “thumb” and “fingers” that bind RNA and a “palm” domain that contains the highly-conserved polymerase active site. At a sequence level, this active site (comprised of three distinct, conserved amino acid motifs) and four additional motifs located outside of the active site show a high degree of sequence conservation.

Advances over the past fifteen years in protein production (notably eukaryotic cell culture) and protein structural characterization (most recently, cryoEM) has led to an abundance of polymerase and RdRp structures. Analysis of these structures has shown that extensive *structural* conservation exists that extends beyond the core regions of sequence alignment alone, and that such conservation extends to other classes of related polymerases, for example RNA-dependent DNA polymerases (RdDps – i.e., reverse transcriptases) from group II introns/retrotransposons and retroviruses (e.g., HIV-1).

The advent of high-throughput sequencing, virus surveillance, and broad metagenomic sampling has led to an explosion of the number of sequences arising from RNA viruses – many of which remain uncultured, uncharacterised, and formally unclassified. Such data has been used – albeit controversially – to carry out large-scale sequence alignment and phylogeny analysis in order to reconstruct the evolutionary history of RNA viruses via the conserved RdRp. This analysis supported the hypothesis that the first RNA viruses were ssRNA(+) viruses that evolved from an ancestral retrotransposon when its reverse transcriptase acquired the ability to synthesize RNA directly, thus removing the need to replicate via a DNA intermediate. The phylogenetic analysis also suggests that dsRNA viruses evolved independently twice from ssRNA(+) viruses, with further evolution of one group of dsRNA viruses giving rise to ssRNA(−) viruses.

From the perspective of viral transcription, two observations can be made if the broad groupings of viruses hold true, irrespective of the precise finer-level tree structures: first, that a “transcription-first” lifecycle has emerged independently at least twice, in the form of dsRNA viruses that package their viral RdRp and undergo an obligatory transcription step to generate mRNA for translation. Second, that RdRps which carry out specialized transcription functions, distinct from genome replication, are widely distributed across ssRNA(+) virus branches. Such a distribution would suggest that specialized transcription (vs. replication) is intrinsic to viral RdRps – either in its ability to evolve independently, or as a common function of ancestral RdRps that was lost in virus families that do not utilize this step.

Different RdRp and Template Conformations Distinguish Transcription from Replication

The initiation of RNA synthesis *de novo* is typically rate-limiting for templated nucleic acid polymerases, since it requires binding a single initiating NTP and holding it in the active site until a second NTP may be bound and polymerized into a nascent dinucleotide transcript. In order to initiate transcription, RdRps may either prime transcription using viral or host-derived RNA fragments, or may attempt to facilitate *de novo* synthesis themselves.

There are distinct requirements for either strategy: RdRps that use a primer to initiate transcription must be able to accommodate double-stranded primer:template RNA within the core of the polymerase during initiation – whether RNA or RNA-protein (U-VPg) – and typically have a thumb and fingers arrangement to accommodate this. They may also position residues at the core of the RdRp to facilitate correct primer alignment (or re-alignment) against the RNA template. In contrast, RdRps that initiate transcription *de novo* usually contain a “priming loop” that is inserted into the active site and stabilises the template: incoming

NTP, often by providing an aromatic residue against which the NTP may stack. Intriguingly, while this approach of *de novo* initiation is conserved, the actual priming loop structures themselves are not: RdRp priming loops may be attached to the thumb in some ssRNA(+) and ssRNA(−) viruses, or the palm in some dsRNA viruses. This situation implies convergent evolution gave rise to these structures – a scenario that is mirrored in a comparison between transcription initiation by prokaryotic and eukaryotic DdRps: the finger domain of the *E. coli* RNA polymerase transcription factor σ^{70} and the B reader loop of eukaryotic RNA Polymerase II transcription factor II B (TFIIB) perform the same function, but are positioned overall in different orientations.

In segmented ssRNA(−) viruses, both primer-dependent and *de novo* initiation are employed by the RdRp, and used to distinguish between transcription (using host-derived primers containing a 5' cap) and viral genome replication (initiated *de novo* with the assistance of a priming loop). This dual function requires structural flexibility in the RdRp in order to accommodate both functions – reflected in the considerable rearrangements observed in polymerase and accessory domains between transcriptase and replicase structures.

Conformational flexibility is also required of RdRps from ssRNA(+) viruses that carry out transcription through the generation of sgRNAs, during which the RdRp must pause transcription, accommodate and hold the nascent transcript while disengaging from the template and re-engaging downstream to resume transcription. This process, often considered a form of intramolecular RNA recombination, can also be imagined as a form of primer-dependent (re-)initiation of transcription downstream of the original transcription start site.

In all cases, multiple factors exist that promote the RdRp to “switch” between replication and transcription functions – a process which can be RNA-directed, protein-directed, or a combination of the two. In the case of ssRNA(+) viruses, RNA structure and sequence complementarity drive sgRNA generation, while in segmented ssRNA(−) viruses, a distinct RNA structure in the RdRp-bound promoter of the genome's complementary (+) sense replication intermediate alters RdRp conformation to prevent transcription and promote replication.

Protein factors that regulate RdRp behavior can be virus- or host-encoded, and are fundamentally linked to the progression and regulation of the viral lifecycle. In alphaviruses, a ssRNA(+) virus, for example, proteolytic processing of the polyprotein cofactor of RdRp triggers transcription. In VSV, a non-segmented ssRNA(−) virus, the RdRp initially binds to host elongation factor 1- α (EF1- α), leading to transcription of viral proteins. Once expressed, viral N protein displaces EF1- α in order to generate a replication-competent RdRp complex. Similarly, in influenza A virus, a segmented ssRNA(−) virus, the RdRp initially binds to host Pol II, locking the RdRp in its transcription-competent conformation. Subsequently, RdRp binding to a second newly-expressed RdRp in complex with a host protein (ANP32) drives formation of a replication-competent RdRp conformation.

RdRps Can Coordinate Transcription, Capping, and Polyadenylation

The adoption of a specific transcription-competent conformation by RdRps is coupled with rearrangements that promote core transcriptional behaviors, and, for viruses that require them, is also coupled with the addition of 5' caps and 3' poly(A) tails to viral mRNA. Core changes in RdRp activity often include fundamental changes to properties of polymerization, such as processivity. These changes can act to promote internal transcription initiation and termination on non-segmented ssRNA(−) genomes, to permit RNA editing by the RdRp, and to favor RdRp pausing and “jumping” to generate sgRNAs on ssRNA(+) genomes.

In eukaryotes, the addition of a 5'-cap to nascent mRNAs is physically coupled to Pol II transcription – a process that has convergently evolved in many RNA viruses. Viruses that encode their own capping machinery may either recruit viral capping enzymes to the RdRp via specific interactions, or encode the capping machinery and the RdRp as a single polypeptide. Such an arrangement (Fig. 2) is present in the RdRps of some ssRNA(+) and ssRNA(−) viruses that synthesize their caps *de novo* using

Fig. 2 Domain structures of cap-synthesizing and cap-snatching polymerases of positive-strand and negative-strand RNA viruses. Positive-strand viruses such as dengue virus (Flaviviridae, DENV), encode single-polypeptide cap-synthesizing polymerases, which are composed of a combined capping (CAP/PNRTase) and methyltransferase (MT) domain, a flexible linker (FL) that recruits additional viral proteins, and a RNA-dependent RNA polymerase (RdRp) domain. Nonsegmented negative-strand RNA viruses such as rabies virus (Rhabdoviridae, RABV) encode single-polypeptide cap-synthesizing polymerases, which are composed of the RNA-dependent RNA polymerase (RdRp) domain, capping (CAP / PNRTase) domain, connector domain (CD), methyltransferase (MT) domain, and C-terminal domain (CTD). Segmented negative-strand RNA viruses such as La Crosse virus (LACV) and influenza A virus (IAV) encode single-polypeptide (LACV) or multisubunit (IAV) cap-snatching polymerases with RdRp, cap-binding, and endonuclease activities. The IAV polymerase is composed of polymerase acidic (PA) (endonuclease), polymerase basic 1 (PB1) (RdRp), and polymerase basic 2 (PB2) (cap-binding) subunits.

polyribonucleotidyl transferase (PRNTase) and methyltransferase (MTase) activities, as well as in those ssRNA(–) viruses that instead acquire already-capped RNA fragments from the 5′ end of host RNAs to use as primers for viral transcription via a capping domain and an endonuclease domain – a process referred to as “cap-snatching”.

Recent advances in protein structure determination have shown that in some viruses, capping and transcription are so closely coupled that a single channel between the RdRp active site and the capping active site is generated – again, an arrangement adopted by the (structurally-unrelated) host Pol II and capping machinery. A closely-coordinated mechanism is also used by cap-snatching RdRps, which must position their newly-acquired 5′-capped primers precisely to the RdRp active site following endonuclease cleavage.

Polyadenylation can also be achieved by multiple mechanisms. In some ssRNA(+) viruses, the poly(A) tail can be fully encoded in genome sequence itself, whereas in others the mechanism appears to be more elaborate, with separate proteins possessing intrinsic polyadenylation capabilities. In human coronavirus 229E, for example, nsp8 has 3′-terminal adenylyl-transferase (TATase) activity – given that nsp7 & nsp8 complex with the RdRp (nsp12) to form a replicase, these activities are likely coupled. In ssRNA(–) viruses, however, the RdRp synthesizes the poly(A) tail itself by “stuttering” on a U-rich tract at the end of each gene. For segmented ssRNA(–) viruses such as influenza A virus, this process is facilitated by RNA/RdRp contacts: as the RdRp approaches the 5′ end of the template during transcription, the 5′-terminal promoter remains tightly bound to the RdRp, sterically preventing transcription beyond the poly(U) tract that is positioned in the RdRp active site.

Prospective

As we have discussed here, viruses adopt a wide range of transcription strategies to ensure efficient expression of their genes. The exact strategy employed by a virus depends in part on its lifecycle and how it interacts with its host – a process that is not strictly one-directional, since both viruses and hosts have co-existed and co-evolved. Indeed, it is tempting to speculate that transcription strategies available to a given virus may be a direct product of its evolutionary history. Poxviruses, for example, contain large genomes that encode for many genes and functions also found in host cells (e.g., DdRp, PAP), leading some to suggest that poxviruses originate from an intracellular eukaryotic parasite that lost its own protein-production capacity – while others have suggested that the ancestral poxvirus evolved to efficiently carry out horizontal gene transfer and simply accumulated a large genome as a result. Such evolution might also apply at the level of individual genomic elements: for example, it has been posited that RNA motifs such as IRESes are remnants of a (pre-transcriptional) “RNA world”, rather than a more recently-evolved mechanism to subvert canonical transcription and translation.

The theme of viral subversion is recurrent: while DNA virus transcription broadly resembles host transcription, RNA viruses (which by their very existence subvert the central dogma of molecular biology) adopt a diverse set of approaches to generate mRNA. As is so often the case in virology, there are further “exceptions to these exceptions”: Hepatitis delta virus (a circular ssRNA (–) satellite virus that depends on co-infection with hepatitis B virus) uses host Pol II (normally a DdRp) to replicate rather than an RdRp; Infectious bursal disease virus (IBDV, a dsRNA virus) has a rearranged order of RdRp catalytic motifs, which are otherwise absolutely conserved.

Our understanding of viruses and transcription has increased considerably in recent years, driven in a large part by the advent of high-throughput sequencing and powerful structural imaging that offer unprecedented insights into the atomic details of macromolecular transcription complexes and their mechanisms. Concurrently, our understanding of host cell transcription and gene expression has increased, leading to the discovery of host gene-encoded IRESes and 3′-end structures to enhance expression, as well as RNA editing and slippage behaviors by host RNA polymerases. Such findings suggest that the diverse mechanisms of viral transcription discussed here are not quite as unique as previously imagined.

Introduction

Viruses are obligate intracellular parasites and are absolutely dependent upon the protein synthesis apparatus of the host-cell. Upon infection and the initiation of the virus replication cycle, the biogenesis of virus proteins requires the sequestration of the infected-cell resources (translational apparatus, aminoacyl-tRNAs, rNTPs) - resulting in a 'competition' for these resources between viral and host-cell mRNAs. Viruses have evolved many, diverse, mechanisms to supplant the 'canonical' translation of host-cell proteins (see below), including mRNA processing/export from the nucleus, mRNA stability and primarily the initiation, but also the elongation and termination stages of translation. Dominance of the virus mRNAs in this competition serves to both maximize virus particle production and to inhibit the innate immune system: secretion of cytokines from the infected-cell signals surrounding, uninfected, cells to enter the 'antiviral state' and recruits immune cells to sites of infection. Virus genomes have also evolved to encode (1) *cis*-acting RNA elements which confer a 7-methylguanosine (m^7G) cap-independent mode of translation, (2) translational enhancers, (3) elements that increase the coding capacity of their genomes, or, (4) to regulate virus protein biogenesis. Translation imposes a high bioenergetic cost upon cells and cellular stress (e.g., metabolite starvation, hypoxia, endoplasmic reticulum (ER) cargo overload, toxins and virus infection) has led to the cell evolving mechanisms to reduce canonical translational activity during stress. Proteins required during stress or involved in stress recovery may be preferentially translated *via* non-canonical translational mechanisms: there are clear parallels between the strategies that host-cells and viruses employ to shut-down canonical host-cell mRNA translation and the use of alternative, non-canonical, translational mechanisms. In this chapter we will provide an over-view of the wide range of mechanisms viruses employ to radically alter the translational 'landscape' of the infected cell to maximize the biogenesis of virus replication and encapsidation proteins.

Canonical or Cap-Dependent mRNA Translation

To discuss the various mechanisms by which viruses subvert the host-cell translational apparatus, it is worthwhile outlining the main features of host-cell mRNA canonical translation. This refers to the process by which the large majority of cellular mRNAs, which comprise a m^7G 'cap' structure at the 5' terminus and a poly(A) tail at the 3' terminus, are translated. The first stage in translation is initiation - a key stage in which the cell responds to various forms of stress to reduce translational activity.

The Initiation Phase

The mRNA 5' cap structure is bound by eukaryotic initiation factor eIF4E. This complex binds to eIF4G - referred-to as a 'scaffolding' protein. This new complex, in turn, binds eIF4A (an RNA helicase). eIF4F is the term for the complex comprising eIF4A, eIF4E, and eIF4G. eIF4B (4A co-factor) is then bound. eIF4G also binds poly(A) binding protein (PABP), bound to the 3' poly(A) mRNA tail, leading to the circularization of the mRNA such that the sites of initiation and termination become proximal. The activity of eIF4E is regulated by phosphorylation at Ser²⁰⁹ by the MAPK-interacting serine/threonine-protein kinase (MNK). The association of MNK with eIF4G is essential for eIF4E phosphorylation. This complex of mRNA and initiation factors then binds the 43S preinitiation complex comprising the small ribosomal subunit (40S) bound to the initiation factors eIF3, eIF1, eIF1A, eIF5 and the ternary complex [eIF2•Met•tRNA_i•GTP] ([Fig. 1, Panel A](#)).

Protein Kinase R (PKR)

Initiation is regulated by the cell at two key stages, the phosphorylation of eIF2 α and the sequestration of eIF4E by eIF4E binding proteins (see below). The GDP-bound form of eIF2 cannot bind Met-tRNA_i and is converted by eIF2B (a guanine exchange factor) to the GTP-bound form, which now binds Met-tRNA_i. Phosphorylation of the alpha subunit of eIF2 (eIF2 α) converts it from a substrate for eIF2B to a competitive inhibitor. Since eIF2B is only present in limiting amounts (10–20 fold less than eIF2), proportionally small changes in eIF2 α phosphorylation have a large effect on initiation: the phosphorylation status of eIF2 α is a key regulator of initiation. eIF2 α is phosphorylated by four different cellular kinases, notably here protein kinase R (PKR or eIF2 α K2). This kinase is activated by double-stranded RNA (dsRNA) - a pathogen associated pattern (PAMP) produced during viral infection. Viruses have evolved proteins/protein domains which may either inhibit PKR activation or dimerization, degrade PKR, sequester dsRNA, synthesize PKR pseudo-

Fig. 1 Schematic showing the association of the various eukaryotic initiation factors (eIFs) in association with the mRNA and the 40S ribosomal small subunit – comprising canonical initiation of translation (Panel A). The binding sites of poly(A) binding protein (PABP), eIFs and MNK on the ‘scaffolding’ protein eIF4G are shown, together with the site where the picornavirus proteinases cleave eIF4G (Panel B).

substrates or activate antagonist phosphatases (reviewed by [García *et al.*, 2006](#); [Langland *et al.*, 2006](#)). Conversely, in the case of the positive (+ve) sense, single-stranded (ss) RNA alphaviruses Sindbis and Semliki Forest viruses, eIF2 is highly phosphorylated within infected cells, shutting off cellular mRNA translation - although virus mRNA is translated. RNA structures in the 5' region of the sub-genomic mRNA are involved in conferring eIF2-independent translation within infected mammalian cells, whereas mutation of RNA structures in the long 3' UTR had little effect upon translation of the genomic and sub-genomic RNAs in mammalian cells, but was highly suppressed in mosquito cells (reviewed by [Carrasco *et al.*, 2018](#)).

Initiation factor eIF4E

A second mechanism of regulation of initiation is the sequestration of eIF4E by eIF4E binding proteins (eIF4E-BPs). The binding of eIF4E-BPs to eIF4E does not inhibit eIF4E binding mRNA cap structures, but inhibits the binding of the mRNA-bound eIF4E to eIF4G: the binding of eIF4G and eIF4E-BP to eIF4E is mutually exclusive. The eIF4E binding activity of eIF4E-BPs is regulated by phosphorylation: in their hyperphosphorylated form eIF4E-BPs cannot bind eIF4E. eIF4E-BPs become hyperphosphorylated at multiple sites following treatment with a variety of extracellular stimuli. Both eIF4E and eIF4E-BPs are targets for viruses. The 100K adenovirus viral protein blocks MNK1 phosphorylation of eIF4E, directly regulating eIF4E activity ([Cuesta *et al.*, 2000](#)). Infection by the picornavirus Encephalomyocarditis Virus (EMCV; cardiovirus A) leads to dephosphorylation of eIF4E-BP1 - which then sequesters eIF4E ([Gingras *et al.*, 1996](#)). Infection by another picornavirus, enterovirus 71 (EV-A71), induces the synthesis of microRNA 141 (miRNA-141) which inhibits the expression of eIF4E ([Ho *et al.*, 2011](#)). Indeed, eIF4E can be replaced or displaced by virus proteins to promote their translation: the arenavirus Junin virus (JUNV) N protein replaces eIF4E, the lentivirus human immunodeficiency virus 1 (HIV-1) promotes the binding of the dead box helicase DDX3 to the eIF4F complex thereby displacing eIF4E, whilst the RING finger Z protein of another arenavirus, lymphocytic choriomeningitis virus (LCMV), directly binds to and blocks eIF4E function (reviewed by [Montero *et al.*, 2015](#)).

Scanning and assembly of the 80S ribosome

The preinitiation complex then scans from the 5' position along the mRNA 5' untranslated region (5' UTR) until encountering the first initiation (AUG) codon. RNA secondary structures present in the 5' UTR are unwound by eIF4A/eIF4B. The mRNA channel is kept in an open conformation by eIF1/eIF1A which also plays an important role in recognition of the AUG initiation codon and flanking nucleotides. The complex pauses at the AUG and eIF5 triggers hydrolysis of GTP bound to eIF2 and the 40S subunit adopts a closed conformation: the ribosomal A-site is empty with Met-tRNA_i occupying the P-site. The large 60S ribosomal subunit associates (catalyzed by eIF5B/GTP) to form the 80S ribosome, this assembly process displacing factors eIF2•GDP, eIF5, eIF3 and eIF1.

Elongation and Termination Phases

Translation now enters the second phase - elongation. Elongation factor eEF1A•GTP-bound aminoacyl-tRNAs enter the vacant A-site where the cognate aminoacyl-tRNA: mRNA codon interaction binds the correct aminoacyl-tRNA into the A-site. GTP is hydrolyzed and eEF1A•GDP released. The peptide bond is formed and translocation occurs: (1) the peptidyl-tRNA (now in the A-site) is translocated from the A- to P-site, concomitant with (2) the deacylated tRNA translocated from the P- to E-site, and, (3) the ribosome translocated one codon along the mRNA. The A-site is now vacant allowing ingress of the next (cognate) aminoacyl-tRNA. Translocation is catalyzed by eEF2•GTP: GTP is hydrolyzed and, following translocation, eEF2•GDP is released. The activity of eEF2 is regulated by a specific calcium/calmodulin dependent kinase, eEF2 kinase (eEF2-K). The activity of eEF2-K is regulated by a series of stress signaling pathways: increased stress signaling produces increased eEF2 phosphorylation and leads to reduced ribosome processivity. The ribosome continues the codon by codon progression through the mRNA open reading frame (ORF) until a termination codon (UAA, UAG or UGA) enters the A-site. In this third phase of translation, all three stop codons are recognized by eukaryotic release factor eRF1 which uses an activated water molecule to hydrolyze the ester linkage between the (completed) peptide and tRNA, located in the P-site. The nascent protein is released with the release of eRF1 being accelerated by eRF3•GTP.

Canonical (Cap-Dependent) Initiation of Virus mRNA Translation

In the case of viruses whose mRNAs do utilize 5'-end cap-dependent (canonical) translation, this may be accomplished simply by the transcription of individual genes (DNA viruses), or, in the case of certain RNA viruses the presence of internal promoters/terminators allows the transcription by the RNA-dependent RNA polymerase (RdRp) of monocistronic mRNAs encoded by individual genes - typified by paramyxoviruses and pneumoviruses (-ve sense, ssRNA genomes). Another strategy is encoding different proteins on separate (generally monocistronic) genomic RNA segments - typified by orthomyxoviruses (-ve sense, ssRNA genomes), reoviruses and rotaviruses (dsRNA genomes).

Cellular mRNAs are processed within the nucleus (capping/splicing/polyadenylation). Viruses that replicate within the cytoplasm cannot utilize this cellular capping activity. Such viruses have evolved various strategies to generate m⁷G capped mRNAs: their polymerases comprise domains or subunits with capping activities such as guanylyltransferase (GTase)/RNA guanine-N⁷-methyltransferase (N⁷MTase)/nucleoside 2'-O-methyltransferase (2'OMTase)/RNA: GDP polyribonucleotidyltransferase (PRNTase).

In the case of certain -ve sense ssRNA viruses (e.g., influenza, lassa, hantaa and rift-valley fever viruses) replication occurs within the nucleus and viral mRNAs become capped by a 'cap-snatching' (or 'cap-stealing') mechanism in which the virus polymerase binds to the m⁷G structure of nascent cellular mRNAs, cleaves the mRNA some 10–20 nucleotides downstream, then uses this capped mRNA tract as a primer for transcription of virus mRNAs. Arenaviruses, which replicate within the cytoplasm, are also thought to cap-snatch, structural studies suggesting that the N-terminal domain of the L polymerase comprises a functional cap-snatching endonuclease (Rosenthal *et al.*, 2017).

Virus mRNAs may be polyadenylated by mechanisms such as re-iterative stuttering of the viral polymerase on a poly(U) tract (e.g., influenza, paramyxoviruses), or, by the virus encoding a protein with poly(A) polymerase activity (e.g., DNA pox viruses). In the case of rotaviruses (dsRNA genomes; 11 segments), virus mRNAs from each segment are capped, but not polyadenylated. Rotavirus non-structural protein 3 (NSP3) is, however, a functional analog of cellular PABP. Rotavirus mRNAs have a 3' UTR consensus sequence which is bound by NSP3. The C-terminal domain of this protein binds to eIF4G, competing with PABP for binding to the same site (Fig. 1, Panel B). NSP3, therefore, circularizes rotavirus mRNA translational complexes. However, NSP3 also binds the cellular protein RoXan. The PABP displaced by NSP3 from translational complexes accumulates in the nucleus, a process which requires NSP3-RoXan interaction and, as infection proceeds, increasingly inhibits the translation of host-cell mRNAs (Harb *et al.*, 2008).

Given that (1) both virus and host-cell mRNAs conform to cap-dependent (canonical) initiation of translation, and (2) there is competition between the two types of mRNA for translational resources, how does translation of the former supplant the latter? Naturally, the cap-snatching and PABP displacement mechanisms outlined above contribute to host-cell shut-off, but preferential degradation of cellular mRNA (Beloso *et al.*, 1992), preferential translation of viral mRNA (Park and Katze, 1995), degradation of cellular RNA polymerase II (RNA pol II; Rodriguez *et al.*, 2007), inhibition of the generation cellular pre-mRNA (Nemeroff *et al.*, 1998) and the retention ('imprisonment') of host-cell mRNA in the nucleus (see below) have been proposed (reviewed by Mohr, 2016). In addition, Herpes Simplex Virus 1 (HSV-1) protein ICP27 highly stimulates the export of intronless virus mRNAs: both ICP27 and Human Cytomegalovirus (HCMV) protein UL69 bind directly to viral mRNA and either the export factors Aly/REF or UAP56, consequently directing the export of virus mRNAs (Koffa *et al.*, 2001; Toth and Stamminger, 2008).

In some cases the pool of mRNA inside cells is remodeled: the genomes of poxviruses, herpesviruses and coronaviruses encode proteins that stimulate mRNA decay. The poxvirus vaccinia virus (VACV; dsDNA) encodes proteins which target all stages in cellular protein biogenesis: host-cell mRNA transcription, mRNA processing (splicing/polyadenylation) and mRNA degradation (reviewed by Walsh, 2017). With regards the latter, can virus proteins involved in mRNA degradation differentiate between virus and host-cell mRNAs? VACV expresses two de-capping enzymes (D9 and D10) that remove the cap from both cellular and viral mRNAs (Shors *et al.*, 1999; Parrish and Moss, 2007). As the replication cycle progresses, increasing the relative abundance of virus mRNAs, this lack of discrimination increasingly favors the translation of viral mRNA. Furthermore, degrading virus mRNAs serves

to promote the control of gene expression during the progressive change in transcription from early to intermediate to late virus genes. VACV infection also leads to changes in both the post-translational modification and sub-cellular distribution of certain translation initiation factors, conferring advantages to the translation of VACV over host-cell mRNAs (reviewed by [Dhungel et al., 2020](#)). Notably, RNA viruses have smaller genomes with a much smaller coding capacity. However, in the case of influenza A virus (IAV) it has been shown that the virus-encoded RNA endoribonuclease PA-X plays a major role in the shut-off of host-cell translation ([Hayashi et al., 2015](#)) – probably by stimulating degradation of RNA pol II transcribed (host-cell) mRNA ([Khapersky et al., 2016](#)). In the case of coronaviruses (+ve sense, ssRNA), non-structural protein nsp1 binds to the 40S ribosome subunit of all active translational complexes inducing cleavage of mRNAs – thought to be by activation of a cellular mRNA surveillance pathway (reviewed by [Abernathy and Glaunsinger, 2015](#)).

‘Imprisonment’ of Cellular mRNAs Within the Nucleus

Inhibiting the nuclear mRNA export pathway to bring about the shut-off of translation of cellular mRNAs is a strategy adopted by a wide range of viruses which may use either canonical and non-canonical modes of initiation. DNA viruses replicate within the nucleus (except pox-, asfar- and phycoviruses) and encode genes without introns: virus mRNAs are, therefore, not spliced. Herpes virus protein ICP27 inhibits cellular mRNA splicing, hijacks the RNA export factor REF plus the export receptor NXF1 thereby facilitating the export of virus mRNAs from the nucleus. Other DNA viruses exploit components of the export pathway to promote export of virus mRNAs whilst inhibiting export of cellular mRNAs (reviewed by [Kuss et al., 2013](#)). The strategy of mRNA imprisonment is also used by a wide range of RNA viruses replicating in either the nucleus or the cytoplasm. In the case of the former, the NS1 protein of Influenza A virus was shown to block cellular mRNA export from the nucleus ([Fortes et al., 1994](#)). NS1 affects multiple stages in cellular mRNA processing: NS1 binds to poly(A)-binding protein nuclear 1 (PABPN1) leading to the accumulation of mRNAs with short poly(A) tails which are not exported to the cytoplasm. The rhabdovirus Vesicular Stomatitis Virus (VSV; -ve sense RNA) replicates within the cytoplasm. The VSV matrix M protein bears nuclear localization signals: it is transported into the nucleus where it binds the mRNA export factor Rae1/Mmp41, blocking mRNA export by the disruption of Rae1 function ([Faria et al., 2005](#)). The nsp1 β protein of the arterivirus porcine reproductive and respiratory syndrome virus (PRRSV; +ve sense, ssRNA) brings about the retention of cellular mRNAs within the nucleus and the shut-off of host-cell translation. Mutations within the SAP (SAF-A/B, Acinus and PIAS) motif of nsp1 β destroyed this phenotype ([Han et al., 2017](#)). The L protein of the picornavirus Theiler's Murine Encephalomyelitis Virus (TMEV; cardiiovirus B) imprisons cellular mRNAs by bringing about the hyperphosphorylation of nucleoporins 62 and 98 (Nup62, Nup98; [Delhaye et al., 2004](#); [Ricour et al., 2009](#)). Imprisonment is also brought about by the L protein of the related EMCV, which interacts with Ran GTPase and brings about the hyperphosphorylation of Nup 62, Nup 153 and Nup 214 ([Lidsky et al., 2006](#); [Porter et al., 2006](#); [Bardina et al., 2009](#)). In the case of viruses within the enterovirus genus of the picornaviruses, the polyprotein comprises two proteinase domains – the 2A proteinase (2A^{pro}) and 3CD proteinase (3CD^{pro}). Both proteinases cleave components of the nuclear pore complex: 2A^{pro} degrades Nup358 and Nup214, whilst 3CD^{pro} degrades Nup62 (reviewed by [Flather and Semler, 2015](#)). Since the virus mRNAs discussed above use canonical initiation, the number of targets to suppress the translation of host-cell mRNAs is constrained. It can be seen, however, that viruses have evolved a surprisingly wide range of mechanisms to inhibit manifold steps in the biogenesis, nuclear export and translation of host-cell mRNAs.

Non-Canonical (Cap-Independent) Initiation of Virus mRNA Translation

Internal Ribosome Entry Sites (IRESes)

Although first discovered in picornaviruses, IRESes have subsequently been characterized in other virus families and certain cellular mRNAs. IRESes are RNA secondary structural features which bind ribosomes not at the mRNA 5' cap, but at an internal site within the 5' UTR. Cellular IRESes predominantly occur in the mRNAs of proteins that are important for cell proliferation, differentiation, regulating apoptosis or responding to stress conditions - notably when cap-dependent translation is repressed. The RNA secondary structures of virus IRESes are formed by intra-strand base-pairing within single, contiguous, tracts of RNA - some hundreds of nucleotides long. They are well studied and bioinformatics (RNA folding *in silico*) together with biochemical RNA structural probing studies and mutagenesis reveal four distinct structural classes (see below). In contrast, IRESes in the 5'-UTRs of certain cellular mRNAs are much more heterogeneous: RNA structures may be formed from non-contiguous tracts of RNA and do not fall into clear structural categories as is the case for virus IRESes. By directly interacting with host translational components, virus IRESes by-pass the canonical method of ribosome recruitment: this creates more targets for the virus to suppress canonical initiation and also by-passes many of the constraints of host-cell regulation. This confers a highly effective advantage to virus mRNAs, allowing the complete shut-off of host-cell mRNA translation.

Type I IRESes ([Fig. 2](#)) are encoded by the enterovirus genus of picornaviruses – typified by poliovirus ([Pelletier and Sonenberg, 1988](#)). The 2A proteinase of enteroviruses (2A^{pro}) cleaves eIF4G ([Fig. 1](#), Panel B) such that the eIF4E and eIF4A binding sites are now on separate cleavage products – shutting off canonical initiation. Interestingly, quite a different type of proteinase, the L proteinase (L^{pro}) encoded by the aphthovirus genus of picornaviruses (typified by Foot-and-Mouth Disease Virus; FMDV), cleaves eIF4G at a site highly proximal to enterovirus 2A^{pro} ([Fig. 1](#), Panel B; [Devaney et al., 1988](#)). Type I IRESes interact with the C-terminal cleavage product of eIF4G and require eIF5B, eIF2/Met-tRNA_i, with activity being stimulated by eIF1, eIF1A and eIF4B. IRES *trans*-acting factors (ITAFs) are RNA-binding proteins that alter IRES conformation and promote binding to eIF4G. Ribosome recruited by type I IRESes scan through a ‘spacer’ region in the 5' UTR (~160nts) until the initiating AUG is encountered.

Fig. 2 The RNA structures of the different types of internal ribosome entry sites (IRESes) are shown together with the site of initiation of translation (black boxes). In the case of the type IV IRES, a CCU sequence (part of pseudoknot 1; PK1) is located in the ribosome P-site and acts as a molecular mimic of tRNA, whilst a GGC codon (encoding glycine) is located in the ribosome A-site.

Type II IRESes are encoded by the cardiovirus genus of picornaviruses - typified by EMCV (Jang *et al.*, 1988). In this case eIF4G is not cleaved: like type I IRESes the translation factors/ITAFs mentioned above are required. Interestingly in another picornavirus genus – the hepatoviruses (typified by hepatitis A virus; HAV), IRES activity in hepatoma cell extracts is higher in comparison to extracts derived from a non-hepatic line (Sadahiro *et al.*, 2018). Ribosomes recruited by type II IRESes bind proximal to the initiating AUG and little, if any, scanning takes place.

Type III IRESes encoded by pestiviruses (typified by Hepatitis C Virus; HCV) interact with both eIF3 and the 40S ribosome thereby by-passing eIF4F altogether (Pestova *et al.*, 1998): a process analogous to ribosome binding by Shine–Dalgarno sequences in bacteria. Generally, type III IRESs require eIF3, eIF5B and the eIF2/Met-tRNA_i ternary complex. Here the initiating AUG codon is directly placed into the ribosomal P-site with no scanning (reviewed by Lukavsky, 2009).

Type IV IRESes encoded by the *Dicistroviridae* (typified by Cricket Paralysis Virus; CrPV) are located in an intergenic region (IGR) between OR1 (non-structural polyprotein) and ORF2 (structural polyprotein), referred-to as an IGR-IRES. Here, direct interaction with the 40S subunit occurs removing the necessity of canonical initiation factors (Wilson *et al.*, 2000; Jan and Sarnow, 2002). This binding leads to changes in the conformation of the 40S subunit such that the 60S subunit associates to form 80S ribosomes. A CCU sequence (part of pseudoknot 1; PK1) is located in the ribosome P-site – acting as a molecular mimic of tRNA, whilst a GGC codon (encoding glycine) is located in the ribosome A-site (Butcher and Jan, 2016). When cognate Gly-tRNA•GTP•eEF1A enters the A-site, base-pairing occurs, then a ‘pseudo-translocation’ of the Gly-tRNA into the P-site allows the elongation phase to

proceed: the N-terminal residue of the nascent ORF2 polypeptide being glycine rather than methionine. In a single additional base-pairing within PK1, the first guanine of the GGC codon is sequestered and a GCG (encoding alanine) occupies the A-site: pseudo-translocation occurs as before and now a new ORF (ORF_x) is translated with an N-terminal alanine (Ren *et al.*, 2012).

In contrast to the complex RNA secondary structures outlined above, simpler structures may also promote cap-independent translation. The 5' UTR leader of Tobacco Etch Virus (TEV; potyvirus) is 143 nucleotides long comprising two domains each forming an RNA pseudoknot (PK1 and PK2; Gallie, 2001), although bioinformatic analyses suggest the presence of a third pseudoknot (Domashevskiy and Cheng, 2015). PK1 binds eIF4G, promoting cap-independent translation. Complementarity was noted between the loop 3 of PK1 and a region within 18S ribosomal RNA (rRNA). Mutations introduced within loop 3 (designed to disrupt potential base-pairing with 18S rRNA) reduced cap-independent translation, whereas mutations which preserved base-pairing had minimal effects (Zeenko and Gallie, 2005). Together, these data indicate the TEV 5' UTR promotes cap-independent translation by providing a functional substitute for a 5'-cap structure.

Cap-Independent Translation Enhancers (CITEs)

The genomes of many +ve-stranded RNA plant viruses comprise neither an m⁷G cap structure at their 5' termini nor a poly(A) tail at their 3' termini. Here, unusual mechanisms have evolved to recruit ribosomes to the 5'-end of the genomes and compete with host-cell mRNAs. One strategy employed by tombus- and luteoviruses involves a range of RNA structures sited within, or proximal to, the 3' UTR - termed 3' cap-independent translation enhancers (3' CITEs), greatly enhancing the initiation of translation. Initially characterized in Satellite Tobacco Necrosis Virus (STNV), a 93 bp tract forms a simple RNA structure - a long stem-loop termed a translation enhancer domain (TED; Fig. 3; Danthinne *et al.*, 1993). Other RNA structures are more complex but together fall into six major types, each with individual properties (Fig. 3). All types appear, however, to follow the same mechanism. Firstly, the 3' CITE binds to components of the translation machinery (e.g., eIF4E, eIF4G or 60S subunit: type dependent) and secondly, the RNA structures in the 3' CITE base-pair to elements within the virus 5' UTR - concomitantly translocating these translation components to the 5' UTR (reviewed by Nicholson and White, 2011; Simon and Miller, 2013).

Virus Alternatives to Components of Initiation

An Alternative to the m⁷G Cap Structure: Virus Protein, Genome Linked (VPg)

Many +ve stranded RNA viruses (both animal and plant) do not bear a m⁷G cap, but have either an oligopeptide or a protein covalently bound to the 5' terminus - VPg. In the case of picornaviruses VPg is ~22 amino acids long and acts as a primer for RNA synthesis, but is not essential for viral RNA (vRNA) infectivity (reviewed by Goodfellow, 2011). In the case of caliciviruses, VPg is much larger (13–15 kDa) and removal of VPg from calicivirus RNA decreases infectivity and translation in cell-free systems. Calicivirus VPg interacts with eIF4E, but does not inhibit neither eIF4E-BP1 binding to eIF4E, nor m⁷G caps binding to eIF4E, indicating a unique VPg binding site for eIF4E. It appears, therefore, calicivirus VPg functions as a m⁷G cap 'substitute' in the initiation of calicivirus translation (Goodfellow *et al.*, 2005; reviewed by Goodfellow, 2011). In the case of plant potyviruses, VPg is some 20–22 kDa, but in members of the genus Sobemovirus VPg is smaller (9–13 kDa). Potyvirus VPg binds eIF4E: however, in plants two isoforms of eIF4E are present - eIF4E and eIF(iso)4E. In general, potyviruses utilize only one specific isoform to initiate

Fig. 3 The RNA structures of the different types of cap-independent translation enhancers (CITEs) are shown; translation enhancer domain (TED), barley yellow dwarf virus (BYDV) BYDV-like translation element (BTE), panicum mosaic virus (PMV) PMV-like translation element (PTE), T-shaped structure (TSS) plus the I- and Y-shaped structures.

translation, but some potyviruses can utilize both isoforms. Trimeric complexes of potyvirus VPg-eIF4E-eIF4G are detected suggesting that these plant virus VPgs, like calicivirus VPg, act as m⁷G cap substitute (reviewed by Jiang and Laliberté, 2011).

An alternative to eIF4F

The expression of various reporter genes was enhanced by the bunyavirus nucleocapsid (N) protein. Further work showed: (1) high affinity binding of N to the 5' cap of cellular mRNAs - replacing eIF4E, (2) N binds directly to 43S pre-initiation complexes - functionally replacing eIF4G and (3) N obviates the requirement for the helicase, eIF4A. Bunyavirus N protein replaces, therefore, the cellular eIF4F complex (Mir and Panganiban, 2008).

Ribosome 'Shunting' (Discontinuous Scanning)

First characterized in the plant pararetrovirus Cauliflower mosaic virus (CaMV; Caulimoviridae), ribosome shunting occurs in the 5'-leader region of CaMV pregenomic RNA (pgRNA). In the current model of ribosome shunting, a 43S preinitiation complex binds at the cap structure of pgRNA, scans through the 5'-leader until the initiation codon of a short upstream ORF (uORF) is encountered: the 60S subunit associates and elongation commences. Translation terminates and the 40S subunit shunts over a long RNA secondary structural feature, then 'lands' in a region (characteristically U/A rich) immediately downstream of the RNA structure. Translation then reinitiates at the start codon of the downstream ORF (Fig. 4). Ribosome shunting is observed in all

Fig. 4 Various forms of alternative initiation are shown. Ribosome shunting in which following termination at the short upstream ORF, the 40S subunit shunts over a long RNA secondary structural feature, then 'lands' downstream. Leaky scanning in which proportion of ribosomes do not initiate at the first AUG but continue to scan for the next AUG downstream. Initiation at non-AUG codons may occur at near-cognate codons (e.g., ACG and CUG), recognized by Met-tRNA_i. Reinitiation may occur if a very short ORF (normally <30 codons) is translated and the 40S subunit does not dissociate and resumes scanning.

genera of the Caulimoviridae, but also in the RNA picorna-like virus Rice tungro spherical virus (RTSV; Secoviridae) and certain animal viruses (reviewed by Firth and Brierley, 2012; Pooggin and Ryabova, 2018).

Leaky Scanning

In the 'classical' model of initiation outlined above, the preinitiation complex scans from the 5' cap along the 5' UTR until encountering the first AUG. However, the efficiency of initiation at a particular AUG is affected by the surrounding context, notably bases at the +4 and -3 positions ($X^{-3}nn \underline{A}^{+1}\underline{U}^{+2}\underline{G}^{+3}X^{+4}$; potential initiation codon underlined), with a purine at -3 and a G at +4 being a 'strong Kozak' context. Sub-optimal contexts produce a significant proportion of ribosomes that do not initiate at the first AUG but continue to scan for the next AUG downstream (Kozak, 1986). This is termed 'leaky scanning' and produces a series of potential outcomes. Firstly, if the next AUG initiation codon is in the same reading frame as the first, then initiation at both AUGs produces both a full-length and N-terminally truncated form of the same protein: C-terminally coincident. Secondly, the second AUG may be in a different, but overlapping, reading frame to the first AUG – thereby producing two distinct proteins from the same coding region. Thirdly, translation of sequential, non-overlapping, ORFs (Fig. 4). Leaky scanning is used by a wide range of RNA viruses – both +ve and -ve sense, plant and animal viruses – to produce multiple proteins from a single message. Besides the context proximal to the first AUG, a number of other factors promote leaky scanning (reviewed by Firth and Brierley, 2012).

Initiation at Non-AUGs

The elongation phase commences predominantly, but not exclusively, at AUG codons. Under some circumstances near-cognate codons (e.g., ACG and CUG) can be recognized by Met-tRNA_i. Such recognition normally requires a strong Kozak context and is enhanced by an RNA secondary structural feature (e.g., stem-loop) forming ~14 nts downstream of the initiation codon such that (1) the structure is located at the entrance to the mRNA entry channel and (2) the near-cognate initiation codon is located in the ribosomal P-site (Kozak, 1990). The group of near-cognate codons comprise CUG (most efficient), GUG, ACG, AUU, AUA, AUC and UUG with initiation levels between 2%–30%, creating an appreciable diversity of protein isoforms (reviewed by Touriol *et al.*, 2003). Since initiation at non-AUG codons is relatively inefficient, ribosomes predominantly scan through a non-AUG codon and initiate either at a downstream AUG or near-cognate codon. Thus, RNA viruses may translate single, or multiple, forms of N-terminally extended protein isoforms, or, multiple different proteins from alternative reading frames (Fig. 4). For example, in the paramyxovirus murine respirovirus (formerly Sendai Virus; SeV) a C' protein (215 amino acids) is translated from an in-frame, upstream, ACG codon whilst the C protein (204 amino acids) is translated from a downstream AUG codon. Indeed, the SeV C ORF produces a nested set of four co-C-terminal proteins, C', C, Y1, and Y2, all of which use the same termination codon (UAA; 728), but arise from four different ribosomal initiation sites, C' = ACG (nt 81), and C = AUG (nt 114), Y1 = AUG (nt 183), and Y2 = AUG (nt 201) (Takeuchi *et al.*, 2008).

Ribosome Reinitiation

Following termination, the ribosomal subunits dissociate from one another and the mRNA. If a very short ORF (normally <30 codons) is translated, however, the 40S subunit may not dissociate from the mRNA and resume scanning. If a downstream initiation codon is encountered reinitiation may occur (Fig. 4). This is thought to depend upon certain initiation factors remaining associated with the ribosome whilst the short ORF is translated. Immediately following termination, the 40S subunit cannot reinitiate and during this new scanning phase must re-acquire specific initiation factors – notably the eIF2•Met•tRNA_i•GTP ternary complex to become competent to reinitiate (reviewed by Jackson *et al.*, 2012). Calicivirus genomes comprise a long ORF1, encoding replication proteins, but transcribe a sub-genomic RNA (sgRNA) which encodes ORF2, the major capsid protein, and ORF3 which encodes a small basic protein essential for infectivity. ORFs 2 and 3 overlap: the ORF2 stop codon is proximal to the ORF3 AUG codon, the length of the overlap being species dependent (1–14 nts): in some cases actually overlapping UAA**AUG** or AUG**A** (stop codons underlined, start codons in bold). ORF3 is translated by reinitiation following ORF2 translation. NOTE: this form of reinitiation is quite distinct from reinitiation following translation of an upstream short uORF outlined above. It has been shown that the calicivirus termination-reinitiation process relies upon mRNA motifs normally 40–49nts upstream of the ORF2 termination codon termed the TURBS (termination upstream ribosome-binding site; Meyers, 2003; Luttermann and Meyers, 2007; Pöyry *et al.*, 2007; Napthine *et al.*, 2009). In the case of Feline Calicivirus (FCV) the efficiency of ORF3 translation is also modulated by RNA sequences downstream of the reinitiation site (Habeta *et al.*, 2014). Reinitiation is observed in a wide range of viruses: the orthomyxovirus Influenza Virus B (IVB; segment 7 – M1 and BM2 proteins; Horvath *et al.*, 1990), the pneumovirus Human Respiratory Syncytial Virus (HRSV; M2-1 and M2-2 proteins; Ahmadian *et al.*, 2000), the totivirus Victorivirus (Gag and Pol proteins; Huang and Ghabrial, 1996), the hypoviruses Cryphonectria Hypoviruses 1 and 2 (CHV-1, CHV2; ORFA and ORFB proteins; Shapira *et al.*, 1991), and cauliflower mosaic virus (CaMV; multiple proteins; Fütterer and Hohn, 1991). Detailed discussions of the mechanisms of virus reinitiation are given in Firth and Brierley, 2012 and Gunišová *et al.*, 2018.

Translational 'Recoding': Non-Canonical Elongation and Termination

Translational 'recoding' is taken here to mean the observed translation products do not correspond with predictions made by simple inspection of the nucleotide sequence of the ORF. In general, cellular canonical initiation of translation only allows the synthesis of

one protein from a specific mRNA. Viruses must, however, translate multiple, different, types of protein (encapsidation functions, replication functions etc.) – often from a single ORF – to maximize coding capacity. Furthermore, the various mechanisms involved in translational recoding often provide sophisticated controls over protein biogenesis during the infectious cycle.

Ribosomal Bypassing ('Hopping')

Normally co-linearity exists between the mRNA coding sequences and the translated protein sequence. In the case of bacteriophage T4 *gene 60* (encoding a subunit of the phage topoisomerase), however, ribosomes translate the first 46 codons, bypass (do not translate) the next 50 nucleotides, then resume translation (Huang *et al.*, 1988). Whilst ~100% of ribosomes appear to commence bypassing, only ~50% resume translation of the second ORF. A diverse range of elements contribute to bypassing: (1) the codons at the 'take-off' and 'landing' sites must be identical (GGA), (2) a stop codon (UAG) must be present immediately 3' of the take-off codon, (3) an RNA stem-loop structure formed by the 3' end of ORF1 and the 5' region of the intervening non-coding sequence (Fig. 5) and (4) a cis-acting peptide signal within the nascent ORF1 peptide - positioned within, and thought to interact with, the ribosome exit tunnel. Additional RNA stem-loop structures are formed by sequences encoding the C-terminal region of ORF1 and those encoding the N-terminal region of ORF2 (for simplicity not shown in Fig. 5 - see Agirrezabala *et al.*, 2017). Recent, detailed, analyses of reconstituted translation systems suggested rather than hopping, the ribosome 'slides' over the gap in a rapid and uniformly processive manner – consistent with the observation that elongation factor G (EF-G; the bacterial equivalent to eukaryotic eEF2, mentioned above) promotes bypassing at the expense of GTP hydrolysis (Klimova *et al.*, 2017). Structural analyses showed that during this process the peptidyl-tRNA^{Gly} anticodon remains base-paired with the mRNA codon - the nascent peptide/ribosome exit tunnel interaction anchoring peptidyl-tRNA^{Gly} in the P-site and 'locking' the peptidyl transferase center (PTC) into an inactive conformation, together with a rotation of the 30S small subunit opening the A-site. The conformation of the PTC and the mRNA secondary structure inhibit termination at, and by reading-through, the UAG stop codon and the altered structure of the ribosome is commensurate with sliding along the intervening non-coding sequences (Samatova *et al.*, 2014; Chen *et al.*, 2015; Agirrezabala *et al.*, 2017; Klimova *et al.*, 2017).

Ribosomal 'Frame-Shifting'

The *gag* and *pol* ORFs of avian alpharetrovirus Rous Sarcoma Virus (RSV) overlap by 58 nucleotides prior to the *gag* termination codon, with *pol* in the –1 reading frame with regards *gag*. Translation products comprised both *gag* and a *gag-pol* fusion protein, with *gag* in a ~20 fold excess over *gag-pol* (Jacks and Varmus, 1985; Jacks *et al.*, 1988). Since this discovery, programmed –1 ribosomal frameshifting has been described in many different viruses (reviewed by Firth and Brierley, 2012; Atkins *et al.*, 2016). Eukaryotic –1 frame-shifting mRNA signals comprise two cis-acting elements. Firstly, a 'slippery' sequence with the consensus X-XXY-YYZ (XXX representing identical nucleotides, YYY representing a triplet of A or U whilst Z represents A, C or U) – the –1 frame shift site. Secondly, an RNA structure, some 5–9nts downstream of the slippery sequence, may comprise either a stem-loop or pseudoknot and is required for efficient frame-shifting. It is thought that tandem slippage occurs in which tRNAs in both the ribosomal A- and P-sites detach from the mRNA zero frame (-XXY-YYZ-) and re-base pair with the mRNA in the –1 frame (-XXX-YYY-). In summary, the processivity of the majority of ribosomes is not impeded by the RNA secondary structure and continue elongation until the stop codon is encountered – translating Gag. The processivity of other ribosomes is impeded by the RNA structure, pausing the ribosome over the slippery sequence where a –1 frame-shift switches the ribosome into the *pol* ORF - translating a Gag-Pol fusion protein. This mechanism facilitates the generation of a defined, fixed, ratio of Gag: Gag-Pol optimal for replication and virion assembly. Furthermore, the Gag-Pol fusion protein facilitates targeting of this replication protein into the virion particle (also obviates the need for a separate ORF encoding Pol). This strategy is employed by many +ve strand RNA viruses to produce an optimal ratio of polymerase in comparison with other virus replication proteins (reviewed by Ahlquist, 2006).

Picornavirus particles are non-enveloped icosahedrons formed of 60 copies each of 4 different capsid proteins (VP1–4) encapsidating a single RNA molecule (~7.5–8.5 kb). These capsid proteins, together with the RNA replication proteins, are encoded by a single, long, ORF. It would appear, therefore, that a uniform stoichiometry in the synthesis of all of these proteins would occur throughout the infectious cycle: no possibility of 'early' (replication proteins)/'late' (capsid proteins) control over protein biogenesis. In contrast to the cis-acting elements described above producing a fixed ratio of –1 frame-shifting, recently it has been shown that EMCV and TMEV have evolved a trans-acting –1 frame-shifting mechanism driven by the 2A protein (Fig. 5; Naphthine *et al.*, 2017, 2019). In the early stages of infection the level of 2A is low, but increases throughout the infectious cycle. The 2A protein binds a stem-loop RNA structure present in the genomic region encoding protein 2B, immediately downstream of protein 2A. At the C-terminus of 2A a 'StopGo' recoding event (see below) produces a discontinuity in the polypeptide backbone thereby separating 2A from 2B. However, a shift site (-CCG-GUU-UUU-; underlined) and the stem-loop structure is formed by sequences encoding the N-terminal region of protein 2B. The stem-loop is bound by protein 2A inducing a –1 frame-shift, in the case of EMCV producing a short protein (2B'; 128 amino acids), rather than the remainder of the polyprotein – some 1249 amino acids. In the latter stages of infection, therefore, the cell's resources are increasingly devoted to the synthesis of capsid (rather than RNA replication) proteins thereby increasing the yield of virus particles.

'StopGo'/'Stop Carry-On'/Ribosomal 'Skipping'

A group of oligopeptide sequences collectively known as 2A, mediate a translational recoding event *in cis* known as "ribosome skipping," "StopGo" or "Stop Carry-on" translation (Donnelly *et al.*, 2001a,b; Atkins *et al.*, 2007; Doronina *et al.*, 2008). The function of the 2A sequence was first characterized from the +ve-stranded RNA picornavirus Foot-and-Mouth Disease Virus (FMDV). The 2A oligopeptide

Fig. 5 Translation bypassing occurs when ribosomes translate the first 46 codons of the T4 gene 60 ORF, bypass (do not translate) the next 50 nucleotides, then resume elongation downstream of the 'take-off' RNA stem-loop structure. Programmed ribosomal frameshifting may occur when the ribosome encounters an RNA structure such that the ribosome is paused over the slippery sequence. In the case of EMCV, the 2A virus protein binds a stem-loop increasingly promoting frameshifting as the infectious cycle progresses. In the case of StopGo, the 2A sequence is thought to interact with the ribosome exit tunnel such that the stereochemistry in the peptidyl transferase center is altered: the peptide bond is not formed. The model proposes that prolyl-tRNA exits the A-site, eRF1/3 enters the A-site (at a sense codon) and terminates translation. After exit of eRF1, prolyl-tRNA then re-enters the A-site and is then (pseudo) translocated such that the A-site is now vacant and elongation can resume. Stop codon read-through is influenced by both the particular stop codon and its nucleotide context permitting low-level (0.3%–5%) read-through. The reverse-transcriptase of MuLV binds to eRF1 enhancing read-through of the stop codon at the end of the gag ORF - leading to the translation of a gag-pol fusion protein. Figure panel adapted from Napthine, S., Ling, R., Finch, L.K., *et al.*, 2017. Protein-directed ribosomal frameshifting temporally regulates gene expression. *Nature Communications* 8, 15582.

is only 18 amino acids long (-LLNFDLLKLAGDVESNPG-), delineated by 3C^{pro} post-translational cleavage at its N-terminus and co-translational 'cleavage' at its C-terminus (reviewed by Belsham, 1993). The sequence at the C-terminus of 2A is strongly conserved in FMDV comprising the canonical motif D(V/I)E(S/T)NPG¹P (arrow indicates 'cleavage' site; underlined proline representing the conserved N-terminal residue of protein 2B). The less conserved part of the 2A sequence, located upstream of the motif, was shown to be essential for 2A function (Ryan and Drew, 1994; Sharma *et al.*, 2012). Further analyses showed a similar recoding activity in just the C-terminal region of the longer cardiovirus 2A protein (Donnelly *et al.*, 1997). Early studies showed the FMDV 2A region was not simply a substrate for an FMDV proteinase (L^{pro}, 3C^{pro}), nor a substrate for a host-cell proteinase – 'self-cleavage' was a novel translational effect (Ryan *et al.*, 1989, 1991; Palmenberg *et al.*, 1992).

The model of translational recoding proposes that when a ribosome encounters 2A the nascent 2A oligopeptide sequence interacts with the ribosome exit tunnel altering the conformation of peptidyl-tRNA^{Gly} in the peptidyl transferase center such that the prolyl-tRNA present in the P-site is unable to form a peptide bond. Prolyl-tRNA exits the P-site allowing entry of eukaryotic release factor 1 (eRF1) to enter at the sense codon (proline) and terminate translation. The nascent polypeptide is released and eRF1 exits the A-site, accelerated by eRF3 (Doronina *et al.*, 2008). Prolyl-tRNA then re-enters the A-site and a 'pseudo-translocation' event occurs, mediated by eEF2, translocating the (deacylated) Glycyl-tRNA from the P-site to the exit site (E-site) plus the prolyl-tRNA from the A- to P-site positioning the next in-frame codon in the A-site (Fig. 5). Elongation of the downstream sequences may then proceed. In this manner a discontinuity in the polypeptide backbone (between 2A and 2B) is produced. Active '2A-like' sequences have been shown to be encoded by a wide range of viruses (Donnelly *et al.*, 2001b; Luke *et al.*, 2008). Since 2A/2A like sequences are active in all eukaryotic (but not prokaryotic) systems, they are used for protein co-expression (concatenating ORFs into self-processing polyproteins) in a wide range of biomedical/biotechnological purposes (Luke and Ryan, 2013, 2018).

Ribosome Stop Codon 'Read-Through'

Stop codons (UAA, UAG or UGA) are recognized by release factors which bind into the A-site and use an activated water molecule to hydrolyze the ester linkage between the completed polypeptide and tRNA. In general, this is a highly efficient process, but may be influenced by both the particular stop codon and nucleotide context permitting low-level (0.3%–5%) read-through (Fig. 5; Bertram *et al.*, 2001). Read-through arises from stop codons being read by near cognate or suppressor tRNAs. Viruses use all three types of motif to promote read-through (Beier and Grimm, 2001). The type I motif comprises the six nucleotides immediately downstream of the stop codon (-UAG-CAR-YYA-; R = purine, Y = pyrimidine), utilized by beny- and pomoviruses to produce C-terminally extended forms of the coat protein. Type II motifs comprise a UGA stop codon immediately followed by a triplet of CUA or CCG (Firth *et al.*, 2011) and are utilized by alphaviruses to read-through a stop codon in the replicase gene, although some alphaviruses do not have this internal stop codon. The replicase gene of other viruses tobria-, peclu-, furo- and pomoviruses all have internal stop codons and utilize the type II motif to promote read-through (reviewed by Firth and Brierley, 2012). Type III motifs are more heterogenous, comprising a UAG stop codon, a 3'-adjacent G or purine-rich octanucleotide tract plus a 3' RNA secondary structure. In gammaretrovirus replicase genes, an internal UAG codon together with (1) certain base sequences comprising an 8 nt spacer region separating the UAG from (2) a pseudoknot RNA structure brings about relatively efficient read-through (Alam *et al.*, 1999; Houck-Loomis *et al.*, 2011). However, influential RNA structures may be located some distance from the stop codon: in luteo- and poleroviruses the structure may be 700–750 nts downstream. Indeed, in viruses such as carnation italian ringspot tomosvirus and turnip crinkle carmovirus (CIRV, TCV; Tombusviruses) efficient read-through relies upon a long-range (3.5 kb) interaction between a proximal RNA stem-loop structure and a distal element (Cimino *et al.*, 2011).

In murine leukemia viruses (MuLVs) the polymerase is expressed as a gag-pol precursor by suppression of termination at the UAG stop codon at the end of the gag ORF. The MuLV reverse transcriptase (RT) has been shown to interact with eRF1 thereby enhancing the suppression of termination: the interaction of RT with eRF1 enhances stop codon read-through to control the biogenesis of the gag-pol fusion protein (Orlova *et al.*, 2003).

Virus-Encoded Proteinases

Collectively, viruses encode molecular mimics of serine, thiol and aspartyl cellular proteinases. These virus-encoded proteinases serve to control virus protein biogenesis (temporally and/or spatially) by 'processing' of virus precursor forms into mature products (reviewed in Ryan and Flint, 1997; Tong, 2002; Rodamilans *et al.*, 2018). Importantly, certain proteinases have also evolved to degrade key host-cell proteins – notably initiation factors and proteins involved in the innate immune system. Enterovirus polyproteins comprise two proteinase domains, 2A^{pro} and 3C^{pro}. In the enteroviruses the uncleaved 3C proteinase/3D polymerase (3CD^{pro}) is also a proteinase and in this form, rather than 3C^{pro}, is required for proteolytic processing of the capsid protein precursor P1 (Jore *et al.*, 1988). Alternative polyprotein processing pathways can, therefore, be used to control protein biogenesis. As outlined above, processing leads to the generation of either 3C^{pro} and 3D^{pol} as individual entities, or, 3CD^{pro} where the 3D^{pol} component of the uncleaved fusion protein acts to modify the substrate specificity of 3C^{pro}.

Another important aspect of virus encoded proteinases is the degradation of key host-cell proteins. As mentioned earlier, both enterovirus 2A^{pro} and 3CD^{pro} proteinases degrade proteins within the nuclear pore complex. Critically, enterovirus 2A^{pro} degrades eIF4G (Fig. 1, Panel B) bringing about 'shut-off' but also degrades PABP (Joachims *et al.*, 1999; Kerekatte *et al.*, 1999). Factors eIF4G and eIF5B are also degraded by 3C^{pro} (de Breyne *et al.*, 2008). FMDV polyproteins also comprise two proteinase domains:

L^{Pro} (a thiol-type proteinase) and 3C^{Pro}, both also cleaving eIF4G (Fig. 1, Panel B; Devaney *et al.*, 1988). Similarly, the calicivirus 3C-like proteinase degrades PABP (Kuyumcu-Martinez *et al.*, 2004). Again, eIF4G and PABP are also degraded by the lentivirus HIV-1 (aspartyl-type) proteinase (Ventoso *et al.*, 2001; Alvarez *et al.*, 2006). It is quite apparent, therefore, that both eIF4G and PABP are common 'targets' for virus-encoded proteinases (reviewed in Smith and Gray, 2010).

Virus proteinases may also control protein biogenesis in both a temporal and spatial manner. HIV RNA contains many post-transcriptional modifications such as N6-methyladenosine (m⁶A), which is thought to reduce viral replication. The m⁶A reader protein YTHDF3 is incorporated into HIV particles and reduces viral infectivity in the next cycle of infection. The Gag-Pol polyprotein is incorporated into the assembling particle through Gag-Gag interactions: concomitant with virus budding, the proteinase is activated to facilitate particle maturation (reviewed by Ganser-Pornillos *et al.*, 2008). Furthermore, the HIV proteinase has recently been shown to cleave YTHDF3 incorporated within virions, increasing the infectivity of the mature particles (Jurczyk *et al.*, 2020).

Another highly important function of virus proteinases is to degrade components of the innate immune response. For example, enterovirus 2A^{Pro} degrades melanoma differentiation-associated gene 5 (MDA5) and mitochondrial antiviral signaling protein (MAVS; Feng *et al.*, 2014), whereas retinoic acid-inducible gene-I (RIG-I) cleavage is observed during infection by various enteroviruses and cardioviruses (Barral *et al.*, 2009; Papon *et al.*, 2009). FMDV L^{Pro} degrades the p65 subunit of NF- κ B (de Los Santos *et al.*, 2007), reduces IRF-3/7 expression (Wang *et al.*, 2010), degrades the Laboratory of Genetics and Physiology 2 (LGP2) protein (Rodríguez Pulido *et al.*, 2018) and MDA5 (Rodríguez Pulido *et al.*, 2020).

MicroRNAs (miRNAs)

miRNAs are small, non-coding RNAs, with an average length of 22 nucleotides that play important roles in the post-transcriptional regulation of cellular gene expression. The viral replication cycles of both DNA and RNA viruses may be enhanced by the evolution of mechanisms that can either degrade, boost, or even hijack cellular miRNAs - one example of each being given below.

In marmoset T-cells latently infected with Herpesvirus saimiri (HVS; gammaherpesvirus), the most abundant virus transcripts are seven small non-coding RNAs termed HSURs (Herpesvirus saimiri U-rich RNAs). HSUR 1 base-pairs with the host-cell miRNA-27 which brings about degradation of miRNA 27 (Cazalla *et al.*, 2010). What advantage does this confer on the virus? miRNA-27 has been shown to decrease the levels of the cell surface signaling protein semaphorin 7A (SEMA7A), the effector cytokine gamma interferon (IFN- γ) and the adapter protein growth factor receptor-bound protein 2 (GRB2; Guo *et al.*, 2014). The repression of T-cell activation by miRNA-27 is relieved by HSUR 1-induced miR-27 degradation.

In contrast, in Epstein-Barr virus (EBV; gammaherpesvirus) latently infected B-cells the expression of host-cell miR-155 is increased ~1000 fold (Lu *et al.*, 2008; Yin *et al.*, 2008). miR-155 plays a number of important immunomodulatory roles in B-cells, T-cells, macrophages, dendritic cells and is an oncogenic miRNA. (O'Connell *et al.*, 2007; Thai *et al.*, 2007). In lymphoblastoid cell-lines or diffuse large B-cell lymphomas positive for EBV, the inhibition or deletion of miR-155 reduces cell growth and promotes apoptosis (Linnstaedt *et al.*, 2010). EBV induced upregulation of host miR-155 may, therefore, be a key aspect in virus-induced oncogenesis.

miR-122 is a highly abundant liver-specific miRNA regulating fatty acid and cholesterol biosynthesis. miR-122 facilitates the replication of hepatitis C virus (HCV) and base-pairs with two conserved binding sites in the HCV IRES. Indeed, miR-122 expression is sufficient to convert non-hepatic cells to become permissive for HCV (Fukuhara *et al.*, 2012; Kambara *et al.*, 2012).

Introduction

Genetic recombination of viruses could be defined as the exchange of fragments of genetic material (DNA or RNA) among parental viral genomes. The result of recombination is a novel genetic entity that carries genetic information in nonparental combinations. Biochemically, recombination is a process of combining or substituting portions of nucleic acid molecules. Recombination has been recognized as an important process leading to genetic diversity of viral genomes upon which natural selection can function. Depending on the category of viruses, recombination can occur at the RNA or DNA levels. Since these processes are different for DNA and RNA viruses, they are described separately.

Recombination in DNA Viruses

In many DNA viruses, genetic recombination is believed to occur by means of cellular DNA recombination machinery. Cellular DNA recombination events are of either homologous (general recombination) or nonhomologous types. The nonhomologous recombination events occur relatively rarely and are promoted by special proteins that interact with special DNA signal sequences. In general, homologous recombination events occur much more often and they are most commonly known as genetic crossing-over that happens in every DNA-based organism during meiosis.

The biochemical pathways responsible for DNA crossing-over are well established. General elements involved in general recombination include DNA sequence identity, complementary base-pairing between double-stranded DNA molecules, heteroduplex formation between the two recombining DNA strands, and specialized recombination enzymes. The best-studied recombination system of *Escherichia coli* involves proteins such as *recA*, and *RecBCD*, and it has led to a large amount of literature. Interestingly, related DNA recombination proteins have been characterized in eukaryotes, including yeast, insects, mammals, and plants.

Yet certain DNA virus species encode their own recombination proteins, and some of these viruses serve as model system with those to study the recombination processes. One of the best-known systems is of certain bacteriophages that recombine independently from the host mechanisms. These independent pathways are used for repairing damaged phage DNA and for exchanging DNA to increase diversity among the related phages. In Enterobacteria phage M13, high recombination frequency was observed within the origin of phage DNA replication in the *E. coli* host. There, the crossovers have occurred at the nucleotide adjacent to the nick at the replication origin, because of joining to a nucleotide at a remote site in the genome. These results implicated a breakage-and-religation mechanism of such apparently illegitimate cross-overs.

Importantly enough, many of these phage recombination mechanisms are analogous to the pathways operating in the host bacteria. For instance, *Rec* proteins of phages T4 and T7 are analogous to bacterial *RecA*, *RecG*, *RuvC*, or *RecBCD* proteins, while *RecE* pathway in the *rac* prophage of *E. coli* K-12 or the phage 1 red system influenced the studies of bacterial systems. A correlation of different stages of DNA recombination with transcription and DNA replication during Enterobacteria phage T4 growth cycle is shown in Fig. 1.

Phage lambda (λ) has a recombination system that can substitute for the *RecF* pathway components in *E. coli*. The Enterobacteria phage λ moves its viral genome into and out of the bacterial chromosome using site-specific recombination. Based on crystal structures of the reaction intermediates, it is clear how the Enterobacteria phage λ integrase interacts with both core and regulatory DNA elements (Fig. 2).

Recombination between viral DNA and host genes can lead to acquisition of cellular genes by DNA viruses. For instance, tRNA genes are present in Enterobacteria phage T4. Interestingly, these tRNA sequences contain introns suggesting that Enterobacteria phage T4 must have passed through a eukaryotic host during evolution. Similar viral–host recombination events were observed for retroviruses in eukaryotic cells.

Genetic recombination in DNA viruses is often studied using functional marker mutations. In single-component DNA viruses recombination occurs by exchanging DNA fragments, whereas in segmented DNA viruses, additional events rely on reassortment of the entire genome segments. This complicates the recombination behavior observed among mutants. One method of recombination analysis utilizes so-called conditional-lethal types, where the cells are infected with two variants and the recombinants are selected after application of nonpermissive conditions (two-factor crosses). This allows the mutants to be organized into complementation groups with the relative positions of mutations being placed on a linear map. Another method is called three-factor crosses. Here three mutations are employed, with crossing-over occurring between two mutations while the third mutation is not selected. This allows for determination of linkage relationships among mutants and of the order of marker mutations. Due to reassortment, both the two-factor and the three-factor crosses are of less use in segmented DNA viruses.

DNA viruses of eukaryotes also recombine their genomic material. For instance, herpes simplex virus (HSV) was found to support recombination while using pairs of temperature-sensitive mutants (two-factor crossings). In fact, a recombination-

Fig. 1 Diagram of the relationship between the Enterobacteria phage T4 transcriptional pattern and the different mechanisms of DNA replication and recombination. (a) Shows the transcripts initiated from early, middle, and late promoters by sequentially modified host RNA polymerase. Hairpins in several early and middle transcripts inhibit the translation of the late genes present on these mRNAs. (b) Depicts the pathways of DNA replication and recombination. Hatched lines represent strands of homologous regions of DNA, and arrows point to positions of endonuclease cuts. Reproduced from Mosig G (1998) Recombination and recombination-dependent DNA replication in enterobacteria phage T4. *Annual Review of Genetics* 32: 379–413, with permission from Annual Reviews.

dependent mechanism of HSV-1 DNA replication has been described. The recombination frequency was proportional to the distance between mutations which suggested the lack of specific signal sequences responsible for the crossing-over. By using three-factor crossing, the HSV system involved two *ts* mutants and a syncytial plaque morphology as an unselectable marker. Similarly, in case of adenoviruses, the host range determined by the helper function of two mutations has been used as a third marker between *ts* mutants. Here, intertypic crosses between *ts* mutants have been identified based on segregation patterns and the restriction enzyme polymorphism.

Epstein-Barr virus (EBV) is a member of the family *Herpesviridae*, and it carries a long double-stranded genomic DNA, that shows a high-degree variation among strains. These variations include single base changes, restriction site polymorphism, insertions, or deletions. Based on tracking these mutations, it was found that some EBV strains arose due to DNA recombination.

Poxviruses represent the largest DNA viruses known (except those of algae and the mimivirus). Homologous recombination was detected in the genome of vaccinia virus (VV), based on the high frequency of intertypic crossovers, the marker rescue, and the sequencing of recombinants. These processes could be both intra- and intermolecular, and they depend on the size of the DNA target. It has been suggested that either viral DNA replication itself or the activity of the viral DNA polymerase might participate in VV DNA recombination. Indeed, some VV proteins with DNA strand transfer activity have been identified.

The DNA genome of Simian virus 40 (SV40, *Papovaviridae*) was found to recombine in somatic cells. The artificially constructed recombinant circular oligomers were used to find high general recombination frequency of SV40 DNA. However, homologous recombination events were rare.

Among plant DNA viruses, genetic recombination was studied in case of geminiviruses and caulimoviruses. The geminiviruses carry a single-stranded DNA genome, composed of either one or two circular DNA molecules. Frequent intermolecular crossing-over events were observed by using mutant combinations. Homologous crossovers were detected to occur intramolecularly between tandem repeats of a geminivirus DNA using agro-infected tobacco plants. The mechanism may involve either homologous crossing-over events or copy-choice processes that rely on template switching by DNA replicase. Moreover, deletions, insertions, and more profound rearrangements have been detected in the geminivirus DNA. These are the illegitimate recombination processes that may involve aberrant breakage-and-religation events or errors in DNA replication, that could occur either inter- or intramolecularly.

Fig. 2 (a) Enterobacteria phage λ integrase compared to the simpler recombinases. Tyrosine recombinases such as Cre have two domains that bind the core recombination sites and carry out recombination on their own. Enterobacteria phage λ integrase has a third, amino-terminal 'arm binding' domain that binds to the arm region of the attachment site. The DNA complex cartoon for Enterobacteria phage λ integrase (lower right) represents the new crystal structures. (b) Integration and excision by Enterobacteria phage λ integrase. The first and second strand exchange cartoons represent the first and second halves of the recombination reaction, respectively. In the first half of integration, for example, Enterobacteria phage λ integrase brings *attP* and *attB* sites together and exchanges the first pair of strands to generate a Holliday junction intermediate. In the second half of the reaction, the Holliday intermediate has isomerized to form a distinct quaternary structure and exchange of the second pair of strands generates recombinant *attL* and *attR* products. Reproduced from Van Duyne GD (2005) Enterobacteria phage λ integrase: Armed for recombination. *Current Biology* 15: R658–R660, with permission from Elsevier.

Cauliflower mosaic virus (CaMV) belongs to a family of plant double-stranded (ds) DNA pararetroviruses that replicate via reverse transcription. A high recombination rate was observed during CaMV infection *in planta*. These crossovers could occur at the DNA level (thus in the nucleus) or at the RNA level (thus more likely during reverse transcription in cytoplasm). However, features such as recombinational hot spots and mismatch repair might indicate replicative (i.e., RNA) step, whereas mismatch repair can occur due to the formation of heteroduplex intermediates and thus suggest DNA recombination. These data further suggest that CaMV has the recombination mechanisms available at both steps of its life cycle. Recombination between CaMV variants and the CaMV transgenic mRNAs has been reported and this is believed to represent the RNA–RNA recombination events that happen during reverse transcription.

Recombination in RNA Viruses

RNA is the genetic material in RNA viruses, and a high mutation rate has been observed for the viral RNA genome. This likely occurs during RNA replication by means of action of an RNA-dependent RNA polymerase enzyme due to either replication errors or because of the replicase switching among viral RNA templates. The terms of classic population genetics do not describe RNA

viruses. A better description of RNA viral populations is provided with a term 'quasispecies' that has been proposed to address a distribution of RNA variants in the infected tissue.

Many of the RNA viruses limit their life cycle to cytoplasm and thus the observed recombination events among RNAs of plus-stranded RNA viruses must occur outside the nucleus. In general, the RNA crossing-over processes are categorized as being either homologous or nonhomologous, but some earlier authors proposed that there are homologous, aberrant homologous, and nonhomologous RNA recombination types. Aberrant homologous recombination involves crossovers between related RNAs, but the crosses occur at not-corresponding sites leading to sequences insertions or deletions. More recently, mechanistic models were utilized to define the following RNA–RNA recombination classes: (1) The 'similarity-essential' recombination, where substantial sequence similarity between the parental RNAs is required as the major RNA determinant; (2) The 'similarity-nonessential' recombination does not require sequence similarity between the parental RNAs, although such regions may be present; and (3) There is the 'similarity-assisted' recombination where sequence similarity can influence the frequency or the recombination sites but additional RNA determinants are also critical.

Genetic RNA recombination has been described in many RNA virus groups. In particular, sequence data reveal RNA rearrangements reflecting RNA–RNA crossover events during RNA virus evolution. For instance, RNA rearrangements were demonstrated in the genomes of dengue virus-type I, flock house virus, hepatitis D virus, bovine viral diarrhea virus, and equine arthritis virus RNA. For plant RNA viruses, this has been demonstrated in potyviruses such as yam mosaic virus, sugarcane yellow leaf virus, and luteoviruses. Experimentally, RNA recombination has been shown to occur in picornaviruses, coronaviruses, or alphaviruses and in the following plant viruses: plum pox virus, cowpea chlorotic mottle virus, alfalfa mosaic virus, cucumber mosaic virus, tobacco mosaic virus, turnip crinkle virus (TCV), and tomato bushy stunt virus (TBSV). It has also been demonstrated in enterobacteria phage Qbeta, in negative RNA viruses, in double-stranded RNA viruses, and in retroviruses, as well as during formation of defective-interfering (DI) RNAs.

Recombination by reassortment was demonstrated for multisegmental animal RNA viruses, such as influenza virus, and in double-stranded reoviruses and orbiviruses. Specifically, the interpretation of two-factor crosses (using, e.g., ts mutants) in reoviruses turned out to be difficult due to recombination. The mutant sites cannot be ordered on a linear map and often no linkage between mutants could be detected.

Interestingly, there are examples of viral RNA recombination with host-derived sequences. These include the presence of unigenic-coding region in bovine diarrhea virus, a sequence from 28S rRNA found in the hemagglutinin gene of influenza virus or a tRNA sequence in Sindbis virus RNA. Also, in plant viruses the host-derived sequences were found in potato leaf-roll virus isolates that carry sequences homologous to an exon of tobacco chloroplast. Chloroplast sequences were found in the actively recombining RNAs of brome mosaic virus (BMV). Several plant viruses were also confirmed to recombine with viral RNA fragments expressed in transgenic plants, including cowpea chlorotic mottle virus, red clover necrotic mottle virus, potato virus Y virus, and plum pox virus.

The existence of several RNA virus recombination systems has made possible the studies of the molecular mechanisms of RNA recombination. The majority of RNA recombination models predict copy-choice mechanisms, either due to primer extension (in flaviviruses, carmoviruses), at the subgenomic promoter regions (BMV, poliovirus), or by strand translocation (in nidoviruses). In retroviruses, there are three copy-choice mechanisms: (1) forced (strong stop) strand transfer, (2) pause-driven strand transfer, and (3) pause-independent (RNA structure-driven) strand transfer. However, in enterobacteria phage Qbeta a breakage-and-religation mechanism has been described. Details of some of these systems are discussed below.

The molecular mechanisms of the formation of both nonhomologous and homologous RNA recombinants have been studied using an efficient system of BMV. In order to increase recombination frequency, the BMV RNA3-based constructs were generated where the 3' noncoding region was extended, while carrying partial deletions. This debilitated the replication of RNA such that the sequence got repaired by recombination with the sequences of other BMV RNA segments. It appeared that short base-paired regions between the two parental BMV RNA molecules could target efficient nonhomologous crossovers. A proposed model predicted that the formation of local RNA–RNA heteroduplexes could function because they brought together the RNA substrates and because they slowed down the approaching replicase enzyme complexes.

These early studies also analyzed the molecular requirements of homologous recombination by inserting the BMV RNA2-derived sequences into the recombination vector. This revealed the accumulation of both precise and imprecise RNA2–RNA3 recombinants and that the recombination frequencies depended upon the composition of nucleotide sequences within the region of recombination. The crossovers tended to happen at stretches of GC-rich regions alternating with AU-rich sequences suggesting the RNA replicase switching between RNA templates. Elements capable of forming strand-specific, stem-loop structures were inserted at the modified 3' noncoding regions of BMV RNA3 and RNA2 in either positive or negative orientations, and various combinations of parental RNAs were tested for patterns of the accumulating recombinant RNA3 components. This provided experimental evidence that homologous recombination between BMV RNAs more likely occurred during positive-rather than negative-strand synthesis.

True homologous recombination crossing-over has been observed among the RNA molecules of the same segments during BMV infections. By using nonselective marker mutations at several positions, it was demonstrated that RNA1 and RNA2 segments crossed-over at 5–10% frequency, whereas the intercistronic region in RNA3 supported an unusually high recombination frequency of 70%. The subsequent use of various deletion constructs has revealed that the high-frequency crossing-over mapped to the subgenomic promoter (sgp) region, and in particular to its internal polyA tract. Further studies have shown that sgp-mediated crossing-over has occurred at the minus-strand level (i.e., during plus-strand synthesis), most likely by discontinuous process,

Fig. 3 Model illustrating the synthesis of sg RNA3a in view of multiple functions of the intergenic region in (–) RNA3. The BMV RdRp enzyme complex (represented by gray ovals) migrates alongside the (–)-strand RNA template and pauses (represented by curved arrows) at the secondary structure or, most notably, at the oligoU tract, leading to the formation of subgenomic sgRNA3a. Yet another molecule of the RdRp enzyme binds to the sgp and initiates the *de novo* synthesis of sgRNA4. Also, the rehybridization of the sgRNA3a oligoA tail to the RNA3 (–) template can resume full-length copying which primes the observed RNA3–RNA3 recombination (5, 69). The (+) and (–) RNA strands are represented by thick lines and both the oligoU tract in the (–) strand template and the oligoA 3' termini are exposed. The stem-and-loop structures adopted by the (+) and the (–) strands upstream to their oligoU (A) tracts are shown. The binding region to protein 1a via the box B of the stem-loop structure in (+) strands is shown. Reproduced from Wierchoslawski R, Urbanowicz A, Dzianott A, Figlerowicz M, and Bujarski JJ (2006) Characterization of a novel 5' subgenomic RNA3a derived from RNA3 of brome mosaic bromovirus. *Journal of Virology* 80: 12357–12366, with permission from American Society for Microbiology.

where the replicase complex detached from one strand and reinitiated on another strand. This process is most likely primed by a sg RNA3a intermediate, which prematurely terminates on the polyU (in minus strand) tract and re-anneals to this region on another minus RNA3 template (Fig. 3). Also, it turned out that the frequency of crossing-over and the process of initiation of transcription of sg RNA4 were reversely linked, suggesting a competition between these two reactions.

The role of replicase proteins in BMV RNA recombination has been studied by using well-characterized 1a and 2a protein mutants. A ts mutation in protein 1a 5' shifted the crossover sites indicating the participation of helicase domain of 1a. Likewise, mutations at several regions of 2a affected the frequency of nonhomologous recombination. The relationship between replication and recombination was studied by using BMV variants that carried mutations in 1a and 2a genes. This revealed that the 1a helicase and the 2a N-terminal or core domains were functionally linked during both processes *in vivo* and *in vitro*. Also, it was shown that the characteristics of homologous and nonhomologous crossovers could be modified separately by mutations at different protein sites. All these studies confirmed the involvement of replicase proteins in recombination and supported the template-switching model.

More recently, the role of host factors in BMV recombination was addressed by using both yeast and *Arabidopsis* systems. In yeast, transient co-expression of two derivatives of BMV genomic RNA3 supported intermolecular homologous recombination at the RNA level but only when parental RNAs carried the *cis*-acting replication signals. The results implied that recombination occurred during RNA replication. In *Arabidopsis*, the use of gene-knock-out mutations in the RNA interference pathway revealed that BMV can recombine according to both the copy-choice template-switching and to the breakage-and-religation mechanisms.

The role of replicase proteins in RNA recombination has also been studied in other RNA viruses. For TCV, a small single-stranded RNA virus, a high-frequency recombination was observed between satellite RNA D and a chimeric subviral RNA C. The crossing-over most likely relied on viral replicase enzyme switching templates during plus-strand synthesis of RNA D which reinitiated RNA elongation on the acceptor minus-strand RNA C template. The participation of replicase proteins was demonstrated *in vitro*, where a chimeric RNA template containing the *in vivo* hot-spot region from RNA D joined to the hot-spot region from RNA C. Structural elements such as a priming stem in RNA C and the replicase binding hairpin, also from RNA C, turned to play key roles during recombination, probably reflecting late steps of RNA recombination such as strand transfer and primer elongation. The host factors related to the host-mediated viral RNA turnover have been found to participate in tombusvirus RNA recombination. The screening of essential yeast genes mutants identified host genes that affected the accumulation of TBSV recombinants, including genes for RNA transcription/metabolism, and for protein metabolism/transport. Suppression of TBSV RNA recombination was observed by the yeast Xrn1p 5'–3' exoribonuclease, likely due to rapid removal of the 5' truncated RNAs, the substrates of recombination. These 5' truncated viral RNAs are generated by host endoribonucleases, such as the Ngl2p endoribonuclease.

Coronavirus RNAs were found to recombine between the genomic and DI RNA molecules. It was postulated that recombination has occurred due to the nonprocessive nature of the coronavirus RNA polymerase enzyme (Fig. 4) and an efficient protocol for targeted recombination has been developed.

Fig. 4 Models for discontinuous transcription from minus-strand sg-length templates in arteriviruses and coronaviruses. These viruses have a common 59 leader sequence on all viral mRNAs. Discontinuous extension of minus-strand RNA synthesis has been proposed as the mechanism to produce sg-length minus-strand templates for transcription. The replicase/transcriptase can attenuate at one of the body TRSs in the 3'-proximal part of the genome, after which the nascent minus strand extends with the anti-leader ('L') sequence. Next, the completed sg-length minus strands serve as templates for transcription. Reproduced from Pasternak AO, Spaan WJM, and Snijder EJ (2006) Nidovirus transcription: How to make sense...? *Journal of General Virology* 87: 1403–1421, with permission from Society for General Microbiology.

Similarly, in nodaviruses, the two-partite RNA viruses, recombination processes were found to occur between RNA segments at a site that potentially could secure base pairing between the nascent strand and the acceptor template. The recombination sites might have been chosen based on factors such as the similarity to the origin of replication or special secondary structures. A postulated model implies the polymerase to interact directly with the acceptor nodavirus RNA template.

A double-stranded RNA *Pseudomonas* phage Phi6 was hypothesized to recombine its RNA based on a copy-choice template switching mechanism, where the crossovers would have occurred inside the virus capsid structures at regions with almost no sequence similarity. Interestingly, the frequency of recombination was enhanced by conditions that prevented the minus-strand synthesis. Experiments were designed to reveal the effects of drift on existing genetic variation by minimizing the influence of variation on beneficial mutation rate. The segmented genome of the *pseudomonas* phage Phi6 has allowed to present the first empirical evidence that the advantage of sex during adaptation increases with the intensity of drift.

The enterobacteria phage Qbeta, a small single-stranded RNA virus, could recombine both *in vivo* and *in vitro*. Here, the mechanism of recombination was not based on a template-switching by the replicase, but rather via a replicase-mediated splicing-type religation of RNA fragments. The system produced nonhomologous recombinants, whereas the frequency of homologous crossovers was low. These data suggested an RNA trans-esterification reaction catalyzed by a conformation acquired by enterobacteria phage Qbeta replicase during RNA synthesis. In summary, the results on various plus-strand RNA virus systems demonstrate the availability of a variety of template-switch mechanisms, the mutual-primer-extension on two overlapping RNA strands, the primer-extension on one full-length RNA strand, as well as both replicative and nonreplicative trans-esterification mechanisms where a piece of another RNA is added to the 3' terminus of an RNA either by viral RdRp or by other enzymes (e.g., RNA ligase), respectively.

The recombination events in retroviruses contribute significantly to genetic variability of these viruses. The crossovers do occur by reverse transcriptase jumpings between the two genomic RNA molecules inside virion capsids. Apparently, the virally encoded reverse transcriptase enzymes have been evolutionarily selected to prone the jumpings between templates during reverse transcription. It turns out that the recombinant jumpings between RNA templates are responsible for both inter- and intramolecular template switchings and also for the formation of defective retroviral genomes. It has been found that the most stable interactions between two copies of retrovirus RNAs were within the 5' nucleotides 1–754. There is experimental evidence demonstrating that the template 'kissing' interactions effectively promote recombination within the HIV-1 5' untranslated region. The possibilities of recombination in retroviruses at the DNA level (of the integrated provirus sequences) were discussed earlier in this article.

Defective-Interfering RNAs

There is a variety of subviral RNA molecules that are linked to viral infections. Those derived from the viral genomic RNAs and interfering with the helper virus accumulation or symptom formation are called as DI RNAs. First reports (in 1954) about DI RNAs coexisting with viral infection was provided by Paul von Magnus with influenza virus. Thereafter, numerous both animal and plant viruses were found to generate DI RNAs. Naturally occurring DI RNAs have been identified in coronavirus infections. These molecules appear to arise by a polymerase strand-switching mechanism. The leader sequence of the DI RNAs was found to switch to the helper-virus derived leader sequence, indicating that helper virus-derived leader was efficiently utilized during DI RNA synthesis. Also, the leader switching likely occurred during positive-strand DI RNA synthesis, and the helper-virus positive-strand RNA synthesis tended to recognize double-stranded RNA structures to produce positive-strand DI RNAs. The parts of the coronavirus RNA required for replication and packaging of the defective RNAs were investigated, with both the 5'- and the 3'-terminal sequences being necessary and sufficient. The coronavirus DI RNAs have been utilized to study the mechanism of site-specific RNA recombination. This process relies on the acquisition of a 5' leader that is normally used for production of numerous

Fig. 5 (a) The outline of different species of genomic RNA and 59 and 39 terminal sgRNAs potentially produced in CTV-infected cells. The positive-sense RNAs are shown in blue and the negative-sense RNAs are shown in red. The wavy line represents the genomic RNA or the plus-sense transcript (blue) and the genomic length minus-sense RNA (red) produced from the plus-sense RNA. The solid green boxes on the genomic negative-stranded RNA represent the sgRNA controller elements. The solid lines represent the full array of plus- and minus-stranded genomic and 39- and 59-terminal sgRNAs potentially produced during replication of CTV. (b, c) Models predicting the generation of 59- and 39-terminal positive- and negative-sense sgRNAs with the controller element present in normal and reverse orientation. One control region is shown for clarity. The wavy blue line represents the transcript (blue) containing the control region (green box) in normal and reverse orientation (the direction of the arrowheads above the controller element indicates the orientation of the controller element). The thick curved arrows represent the transcription termination (vertical direction, red) or promotion (horizontal direction, yellow). The solid blue lines with arrowheads represent the positive-sense 39- and 59-terminal sgRNAs and the solid red line with arrowhead indicates the 39-terminal negative-sense sgRNA. The dashed lines with arrowheads indicate the potential 59 terminal positive (blue)- and negative (red)-sense sgRNAs. Reproduced from Gowda S, Satyanarayana T, Ayllon MA, *et al.* (2001) Characterization of the *cis*-acting elements controlling subgenomic mRNAs of *Citrus tristeza virus*: Production of positive- and negative-stranded 39-terminal and positive-stranded 59 terminal RNAs. *Virology* 286: 134–151, with permission from Elsevier.

coronavirus sg RNAs. Also, these DI RNAs have been used as vehicles for the generation of designed recombinants from the parental coronavirus genome.

In case of plant viruses, tombusviruses and carmoviruses were found to accumulate DI RNAs, which maintain a consistent pattern of rearranged genomic sequences flanked by the 5' and 3' unchanged replication signals. In some cases, the base pairing between a partial nascent strand and the acceptor template can lead to the appearance of the rearranged regions in DI RNAs.

In addition to rearranged DI RNAs, some RNA viruses accumulate defective RNAs due to a single internal deletion in the genomic RNA of the helper virus. Such examples include beet necrotic wheat mosaic furovirus, peanut clump furovirus, clover yellow mosaic potyvirus, sonchus yellow net rhabdovirus, and tomato spotted wilt tospovirus. Features such as the ability to translate or the magnitude of the defective RNA seem to affect the selection of the best-fit sizes of DI RNAs during infection.

Another type of single-deletion DI RNAs are produced during broad bean mottle bromovirus (BBMV) infections from the RNA2 segment. A model has been proposed where local complementary regions bring together the remote parts of RNA2 which then facilitates the crossover events. Similar RNA2-derived DI RNAs have been reported to accumulate during the cucumovirus infections.

The closteroviruses, the largest known plant RNA viruses, form multiple species of defective RNAs, including the citrus tristeza virus defective RNAs that arise from the recombination of a subgenomic RNA with distant 5' portion of the virus genomic RNA (Fig. 5). Apparently, closteroviruses can utilize sg RNAs for the rearrangement of their genomes.

Negative-strand RNA viruses also form DI RNAs. For instance, in vesicular stomatitis virus (VSV), a rhabdovirus, the *cis*-acting RNA replication terminal elements participate in the formation of the 5'-copy-back DI RNAs, reflecting likely communication between distant portions of the VSV genome.

Summary and Conclusions

Genetic recombination is a common phenomenon among both DNA and RNA viruses. The recombination events have been observed based on natural rearrangements of the sequenced viral genomes. Also, experimental systems demonstrate the occurrence of recombination events that play important roles in securing the genetic diversity during viral infection. Different molecular mechanisms are involved in DNA versus RNA viruses. Many DNA viruses utilize host cellular machinery of general homologous recombination (such as meiotic crossing-over), whereas some encode their own proteins that are responsible for recombination. In addition, certain groups of DNA viruses support site-specific (nonhomologous) recombination events. In general, the virus DNA recombination mechanisms seem to involve post-DNA replication molecular events.

For RNA viruses the majority of known homologous and nonhomologous RNA recombination events appear to be integrally linked to RNA replication machinery. Various types of copy-choice (template-switching) mechanisms were proposed to describe the easy formation of RNA recombinants in numerous RNA virus systems. The roles of both special RNA signal sequences and viral proteins have been elucidated, reflecting the variety of the recombination strategies used by RNA virus groups. The involvement of host cell genes in RNA virus recombination has begun to get elucidated in several RNA viruses. Besides replicational copy-choice mechanisms, some RNA viruses use the breakage-and-religation mechanism where viral RNA gets regenerated by religation from RNA fragments, as shown experimentally for Enterobacteria phage Qbeta. New venues of RNA recombination research just emerge including our better understanding of the involvement of RNA *cis*-acting signals, the role of RNA replication, and the importance of cellular host genes such as RNA ribonucleases or RNA interference.

Glossary

Core-like particle (CLP) Subviral particles assembled from recombinantly expressed capsid protein are referred to as core-like particles. They are morphologically similar to authentic cores isolated from viruses or infected cells.

Cryo-EM Cryo-electron microscopy and image reconstruction techniques are used to elucidate the structures of viruses and other macromolecular structures.

Immature virion Viruses usually produce noninfectious particles which require a maturation step in order to form the infectious, mature virus. The maturation step often involves the proteolytic cleavage of a precursor protein.

Nucleocapsid core (NC) Capsid protein packages the nucleic acid genome to form a stable protein–nucleic acid complex which is then enveloped with a lipid bilayer.

Introduction

Viruses have long been distinguished by their physical features, usually visualized by electron microscopy or analyzed biochemically. One feature that has been frequently used to categorize viruses is the presence or absence of a lipid bilayer. Many animal viruses are surrounded by a lipid bilayer that is acquired when the nucleocapsid buds through cell membranes, usually at a late stage of virus assembly. While the protein coat of nonenveloped viruses plays a crucial role in protecting the genome from the environment, for enveloped viruses the lipid membrane partially fulfills this role. The lipid membranes are decorated with virus-encoded envelope proteins that are important for the subsequent infectivity of the virus, although some viruses also incorporate cellular proteins in their membrane. Virus envelopment can take place after the assembly of an intact nucleocapsid structure (betaretroviruses) or capsid assembly and envelopment can occur concomitantly (orthomyxovirus). Specific or nonspecific interactions between the viral envelope glycoproteins and the proteins that make up the nucleocapsid mediate the envelopment of the core or nucleoprotein–nucleic acid complex. Enveloped viruses acquire their lipid bilayer from a variety of locations within the cell, but a given virus will usually bud from one specific cellular membrane (Table 1). Enveloped viruses can take advantage of the cellular secretory pathway in order to assemble and bud out of the cell. In contrast, nonenveloped viruses usually exit infected cells by disrupting the plasma membrane. Thus, budding provides enveloped viruses with a nonlytic method of exiting infected cells, and they must do so while the cell is still alive.

Viral Envelope

The main component of the viral envelope is the host-derived lipid bilayer. The precise composition of this lipid membrane varies, as different viruses acquire their envelopes from different cellular membranes. The choice of membrane from which the virus buds is often determined by the specific targeting and accumulation of the envelope proteins at a particular site in the secretory pathway (Table 1). There are examples of viruses that bud from the plasma membrane (togaviruses, rhabdoviruses, paramyxoviruses, orthomyxoviruses, and retroviruses), endoplasmic reticulum (ER) (coronaviruses and flaviviruses) and the Golgi complex (bunyaviruses). There are also examples of viruses that undergo transient envelopment and reenvelopment (herpesvirus).

Viral proteins are found embedded in the lipid membrane. The majority of these proteins are transmembrane glycoproteins. The viral envelope glycoproteins mediate the interaction of the virus with cell receptors and promote the fusion of the viral and cellular membranes during infection of susceptible cells. Viral glycoproteins are also crucial for the assembly of the virion. They can make important lateral contacts with each other, thus driving oligomerization and also capturing other viral components such as the capsid or matrix protein. The majority of enveloped viruses contain one or more glycoproteins that are usually found as oligomers embedded within the lipid membrane. High-resolution structural information is available for many glycoproteins such as the hemagglutinin and neuraminidase proteins of influenza A virus, the gp120 of HIV, and the E protein of dengue virus. Based on these structural and biochemical studies, it has been shown that most glycoproteins are primed for the conformational changes that are required in order to gain entry to the host cell during an infection.

Some enveloped viruses contain integral membrane proteins that have multiple membrane-spanning regions that oligomerize to form channels in the membrane. The influenza A virus M2 protein forms an ion channel and plays an important role in the assembly and entry of the virus particle. Some viruses such as the retroviruses also incorporate cellular membrane proteins into the viral envelope. In a majority of the cases the host proteins that are present at the sites of assembly or budding are incorporated in a passive, nonselective manner. However, there are examples where the virus actively recruits specific host proteins that may help in evading the defenses of the immune system or enhance infectivity.

Table 1 List of enveloped virus families and the origin of the envelope

Virus family ^a	Membrane
<i>Arenaviridae</i>	Plasma membrane
<i>Arterivirus</i>	Endoplasmic reticulum

Icosahedral Enveloped Viruses: Alphaviruses and Flaviviruses

Alphaviruses, and more recently, flaviviruses have served as model systems to study the assembly and budding of simple enveloped viruses. These positive-strand RNA viruses consist of a single RNA genome that is encapsidated by multiple copies of a capsid protein to form the nucleocapsid core (NC). The envelopment of the NC is mediated by the interaction between the envelope glycoproteins and this core. The assembly and budding of these two simple enveloped viruses will be described in detail in order to present common themes in the assembly of icosahedral enveloped viruses.

Alphavirus Assembly

Alphavirus life cycle

Alphaviruses are members of the family *Togaviridae*, which also includes the genus *Rubivirus*. Alphaviruses enter the host cell by receptor-mediated endocytosis via the clathrin-coated endocytic pathway. Following fusion at low pH with the endosomal membrane, the NC is released into the cytoplasm. The NC has been proposed to uncoat by transfer of capsid proteins (CPs) to ribosomes. This releases the genome RNA into the cytoplasm which is translated to produce the nonstructural proteins. The nonstructural proteins transcribe a negative-sense copy of the genome RNA. This RNA serves as template for genomic and subgenomic RNA. The subgenomic RNA, which is synthesized in greater amounts than the genomic RNA, codes for the structural proteins of the virus. CP is found at the N-terminus of the structural polyprotein, followed by proteins PE2 (E3 + E2), 6K, and E1. Two hundred and forty copies of CP, E2, and E1 assemble to form the alphavirus virion (Fig. 1(a)). The transmembrane E1 glycoprotein functions during entry to mediate the fusion of the viral membrane with that of the endosomal membrane, while the transmembrane E2 glycoprotein is responsible for cell receptor binding. E1 and PE2, a precursor of E2 and E3, are processed together as a heterodimer in the ER and Golgi, and are transported to the cell surface in the form of spikes that are each composed of three heterodimers of E1/E2. E3 serves as a chaperone to promote the correct folding of E2, as well as to prevent the premature fusion of E1 in the acidic environment of the late Golgi. The maturation cleavage of PE2 to generate E3 and E2 by a furin-like protease in a late Golgi compartment primes the glycoprotein spike complex for subsequent fusion during virus entry. The function of 6K is unclear but it does promote infectivity of the particle. A single copy of the genome RNA is packaged by 240 copies of the CP to form an icosahedral NC in the cytoplasm of infected cells. The NC interaction with the E1/E2 trimeric spikes at the plasma membrane results in the budding of the mature virus from the cell membrane.

Fig. 1 Cryo-EM reconstructions and glycoprotein topology of alphaviruses and flaviviruses. (a) Surface shaded view of a Cryo-EM reconstruction of Ross River virus (alphavirus). The glycoprotein envelope shown in blue has been cut away to reveal the lipid bilayer (green) and the nucleocapsid core (orange). (b) Cryo-EM reconstruction of dengue virus (flavivirus). The glycoprotein envelope shown in blue has been cut away to reveal the lipid bilayer (green) and the nucleocapsid core (orange/purple). (c) The topology of the alphavirus glycoproteins is shown. The rectangular cubes represent signal sequences while the cylinders represent stop transfer sequences. The glycosylation sites are represented by branched structures. The arrows indicate cleavage sites. The black arrows indicate signalase cleavage sites, the purple arrow indicates the furin cleavage site, and the red arrow indicates the CP cleavage site. (d) The topology of the flavivirus structural proteins is shown. The rectangular cubes represent signal sequences while the cylinders represent stop transfer sequences. The glycosylation sites are represented by branched structures. The arrows indicate cleavage sites. The black arrows indicate signalase cleavage sites, the purple arrow indicates the furin cleavage site, and the green arrow indicates the NS2B/NS3 (viral protease) cleavage site.

Alphavirus virion structure

Cryo-electron microscopy (cryo-EM) and image reconstruction techniques have revolutionized the understanding of the molecular architecture of alphaviruses (Fig. 1(a)). Studies with Ross River, Semliki Forest, Venezuelan equine encephalitis, Aura, and Sindbis have shown that these viruses consist of an outer protein layer made up of the glycoproteins E1 and E2 (Fig. 1(a) and (c)). The membrane spanning regions of these glycoproteins traverse a host-derived lipid bilayer that surrounds the NC of the virus. The CP and glycoprotein layers interact with one another and are arranged symmetrically in a $T = 4$ icosahedral configuration. Fitting of the atomic coordinates of the ectodomain of E1 and amino acids 106–264 of the CP into the cryo-EM density of Sindbis virus allowed a pseudo-atomic model of the virus to be generated. The fitting of the E1 structure into the cryo-EM density reveals that E1 forms an icosahedral scaffold on the surface of the viral membrane. E1 is positioned almost tangential to the lipid bilayer, whereas E2 has a more radial arrangement. The bulk of E2 lies on top of E1 and caps the fusion peptide, thereby preventing premature fusion with cell membranes. This arrangement of the glycoproteins is in agreement with the function of each protein, where the surface-exposed E2 interacts with cellular receptors and protects E1 until it is required for fusion. The fusion peptide is only exposed when the E1–E2 heterodimer dissociates in the presence of low pH in the endosome. Fitting of amino acids 106–264 of the CP into the cryo-EM density of Sindbis virus showed that each subunit of the projecting pentamers and hexamers (known as capsomeres) observed in the NC layer is made up of the CP protease domain consisting of amino acids 114–264. There is very little interaction between amino acids 114–264 of the CP either within the capsomere or in between capsomeres. Thus, the major contributors to the stability of the NC in the absence of glycoproteins are CP–RNA and RNA–RNA interactions that take place in the RNA–protein layer below the projecting capsomeres.

Alphavirus assembly and budding

Alphavirus virions always contain an NC and it is likely that this promotes and is required for budding through direct interactions with the glycoproteins. Thus, the first step in assembly is for the alphavirus CP to specifically recognize and encapsidate the

Fig. 2 Alphavirus assembly. Two capsid proteins (CPs) bind the encapsidation signal of the genome RNA to form a CP dimer-RNA complex in the cytoplasm. The CP dimer is stabilized by coiled-coil helix I interactions. The subsequent steps of nucleocapsid core assembly have not been elucidated but cores form and accumulate in the cytoplasm. The glycoproteins PE2 and E1 form heterodimers in the endoplasmic reticulum (ER). The glycoproteins are folded, glycosylated, and palmitoylated as they are transported through the ER and Golgi. The PE2-E1 heterodimers form spike complexes [PE2-E1]₃ in the Golgi. E3 is cleaved from the spikes by a furin-like protease before they are transported to the plasma membrane. The NC interacts with the cytoplasmic domain of E2 in the spike complexes, driving the budding of the mature virus from the plasma membrane.

genome RNA to form NCs in the cytoplasm of infected cells (Fig. 2). The N-terminus of the CP (amino acids 1–80, SINV numbering) is largely basic and thought to be involved in charge neutralization of the genome RNA. Amino acids 38–55 are conserved uncharged residues that form a coiled-coil alpha-helix (helix I) important in dimerization of the CP during the assembly process. While the process of virus assembly is difficult to study in the complex cellular environment, the development of an *in vitro* assembly system based on bacterial expression of CP has led to advances in understanding NC assembly. These studies suggest that the initial event of NC assembly is the binding of CP amino acids 81–112 to the encapsidation signal on the genome RNA corresponding to nucleotides 945–1076 (SINV numbering) (Fig. 2). This interaction exposes a second site on the encapsidation signal where another molecule of CP binds and forms a dimer with the first CP molecule. Amino acids 114–264 constitute the previously mentioned chymotrypsin-like serine protease that autoproteolytically cleaves CP from the nascent structural polyprotein. This region is involved in binding residues from the cytoplasmic domain of E2, thus linking the outer icosahedral glycoprotein shell with the NC across the lipid bilayer (Fig. 1(a)).

Other lines of evidence support the dimer model of NC assembly. Helix I of CP, which is required for core accumulation in infected cells, may be functionally substituted by a GCN4 helix that forms dimeric coiled-coil interactions but not by a GCN4 helix that has a propensity to form trimeric coiled-coil interactions. In addition, helix I acts as a checkpoint in NC assembly whereby incompatible helices prevent the formation of core-like particles (CLPs) *in vitro*. Furthermore, a portion of CPs in either NCs or CLPs may be cross-linked into dimers by DMS, a lysine specific cross-linker with a 12 Å cross-linking distance. Cross-linking enabled an assembly deficient helix mutation of CP to assemble into NCs, suggesting that the cross-link can functionally replace the helix interaction.

While assembly of the CP into NCs proceeds in the cytoplasm, the processing and assembly of the glycoproteins occur in the ER and Golgi (Figs. 1(c) and 2). The autocatalytic cleavage of the CP reveals a signal sequence on the N-terminus of the newly cleaved structural polyprotein that directs it to the ER (Fig. 1(c)). PE2 is translocated into the ER until it reaches a 26-amino-acid stop transfer signal which anchors PE2 in the membrane. The C-terminal 33 residues of E2 then act as a second signal sequence to direct the next protein, 6K (55 amino acids), into the ER. 6K possesses a stop transfer sequence which anchors it in the membrane, and the C-terminus of 6K acts as signal sequence for the translocation of E1. E1 is anchored in the ER membrane by a final stop transfer

sequence close to its C-terminus. The release of PE2 and E1 by cellular signalase cleavage allows the formation of PE2-E1 heterodimers in the ER (**Fig. 2**). PE2 and E1 are each glycosylated in all alphaviruses, but the number and location of the modifications vary. In addition to glycosylation, the glycoproteins are palmitoylated in the Golgi apparatus. As the heterodimers are processed and transported through the ER and Golgi, they undergo a series of folding intermediates that are mediated by disulfide exchange and chaperones. Ultimately, they associate to form spikes which are composed of trimers of PE2-E1 dimers (**Fig. 2**).

The final maturation event is the cleavage of PE2 into E3 and E2 by a furin-like protease (**Fig. 2**). This cleavage occurs in a late Golgi or post-Golgi compartment and results in the destabilization of the heterodimer enabling the mature virus to fuse more readily with the target membrane. In most alphaviruses including Sindbis, E3 is released and not found in the mature virion. The final destination for the spike complexes is the plasma membrane, where the cytoplasmic domain of E2 (cdE2) recruits NCs assembled in the cytoplasm (**Fig. 2**). Structural studies show that cdE2 residues Tyr400 and Leu402 bind into a hydrophobic pocket of the CP. Mutation of Tyr400 negatively impacted virus budding, while protein translation and core accumulation were at wild-type levels. This interaction of cdE2 with the hydrophobic pocket in the CP is thought to drive the budding of the mature virus at the cell membrane.

Flavivirus Assembly

Flavivirus life cycle

Flaviviruses belong to the family *Flaviridae* of positive-strand RNA viruses which also consist of the pestiviruses and the hepaciviruses. The flaviviruses comprise more than 70 members including important human pathogens such as yellow fever virus, dengue virus, and West Nile virus. Flaviviruses enter cells via receptor-mediated endocytosis. The low pH environment of the endosomal membrane triggers the conformational change of the envelope glycoprotein which results in the fusion of the viral and endosomal membranes releasing the genome into the cytoplasm. The viral proteins are translated from the RNA genome as a single polyprotein. Signal sequences and stop transfer sequences result in the translocation of the nascent polyprotein to the ER membrane. The polyprotein is processed by a combination of cellular and viral proteases to produce the mature structural and nonstructural proteins. Genome replication and virion assembly occur in ER membrane-bound vesicles. The structural proteins and the genome bud into the lumen of the ER to form the immature virion which is transported through the secretory pathway. Prior to secretion of the virion, a furin cleavage converts the immature virus into the mature, infectious form of the virus.

Flavivirus virion structure

The flavivirus virion is made up of three structural proteins: capsid (C), pre-membrane (prM), and envelope (E) that are translated from the 5' one-third of the RNA genome (**Fig. 1(b)** and **(d)**). Signal sequences at the C-terminus of the C protein and prM serve to translocate prM and E respectively into the ER (**Fig. 1(d)**). The role of the highly basic C protein (12 kDa) is to encapsidate the viral genome during virion assembly. In contrast to the alphavirus CP which exhibits no membrane association, the flavivirus C protein is anchored to the membrane, at least transiently (**Fig. 1(d)**). However, Rubella virus, the sole member of the genus *Rubivirus* within the family *Togaviridae*, has a membrane anchored CP, perhaps indicating a common origin for the *Togaviridae* and *Flaviviridae*. prM is a glycoprotein that associates with the E protein and serves as a chaperone to facilitate the proper folding of E. The immature virions that bud into the ER consist of prM-E heterodimers. prM prevents premature fusion from occurring in the acidic environment of the ER and Golgi. Thus, prM has several functions analogous to the E3 glycoprotein of the alphaviruses. Cleavage of prM into pr and M by a furin-like protease triggers the rearrangement of the prM-E heterodimers into E-E homodimers, resulting in a radical change in size and shape required for the formation of the mature virus particle. The E glycoprotein is responsible for host cell receptor binding and for fusion of the viral and cellular membranes. The E glycoprotein is also critical for the assembly of the virion. High-resolution structures of the ectodomains of several flavivirus E proteins are available. The ectodomain is divided into three domains. Domain II constitutes the dimerization domain as it contains most of the intradimeric contacts between E-E homodimers. Domain II also contains the fusion peptide, a glycine-rich hydrophobic sequence that initiates fusion by insertion into the target cell membrane. Domain III comprises the immunoglobulin-like domain responsible for receptor binding. In addition to the dramatic conformational and translational changes that the E protein undergoes during the virion maturation process, it also changes conformation during membrane fusion. The low pH of the endosome during infection triggers a conformational change which results in the formation of E homotrimers. In this arrangement, the fusion peptides are exposed and available to insert into cellular membranes. Interestingly, the structure of the E protein was found to be very similar to the structure of the Semliki Forest virus E1 protein, the fusion protein of the alphaviruses.

The structures of two flaviviruses, dengue and West Nile virus, have been solved by cryo-EM and image reconstruction techniques and have been shown to be similar (**Fig. 1(b)**). The mature virion is ~50 nm in diameter and exhibits a smooth outer surface in contrast to the alphaviruses which have distinctive spike structures (cf. **Fig. 1(a)** and **(b)**). The E proteins are arranged parallel to the surface of the virus, with 90 E dimers arranged in groups of three to form a 'herringbone' pattern on the viral surface. This arrangement of the E proteins completely covers the surface of the virus, thus rendering the lipid bilayer inaccessible. Domain III of E protrudes slightly from the viral surface, allowing interaction with cell receptors. The membrane-spanning regions of E and M proteins form antiparallel helices while the stem regions are arranged parallel to the membrane.

Fig. 3 Flavivirus assembly. Flavivirus assembly occurs on ER-associated membranes known as vesicle packets. Assembly and genome replication are coupled and the sites of assembly consist of the capsid proteins (C), the glycoproteins prM and E, the RNA genome, and one or more nonstructural proteins and/or host factors. The immature virion buds into the ER and is transported to the Golgi and trans-Golgi network. The glycoproteins are post-translationally modified as the immature virus is transported through the secretory pathway. Furin cleavage of prM results in the formation of the mature virus which then exits the cell by exocytosis.

The immature virus particle exhibits a dramatically different glycoprotein organization compared to the mature virion. Cryo-EM and image reconstruction of dengue and yellow fever virus immature virions have revealed that these particles are larger (~60 nm) and have spikes that protrude from the surface of the virus. These spikes are composed of trimers of prM-E heterodimers. The pr peptide covers the fusion peptide of E in this arrangement, similar to E2 covering E1 in alphaviruses, thus protecting it from premature fusion as the immature particle is transported through the acidic environment of the secretory pathway.

The NC is found below the viral envelope and is composed of a single copy of the genome RNA and multiple copies of the C protein. Cryo-EM reconstructions of the virion have shown that in contrast to the alphaviruses, there is no apparent organization to the flavivirus NC. This may be because there is no direct interaction between the C proteins in the core and the glycoproteins in the viral envelope since the E and M proteins do not penetrate below the inner leaflet of the membrane. Furthermore, no NCs have been observed in the cytoplasm of infected cells and attempts to establish an *in vitro* assembly system analogous to the alphavirus *in vitro* assembly system have failed. The lack of coordination between the C protein and the viral envelope proteins suggests that the assembly of virions is driven by the lateral interactions of the E and M proteins in the viral envelope and not by the C protein. This is supported by the observation that flavivirus infections result in the production of noninfectious subviral particles which are composed of just the viral envelope (E and M) and the lipid bilayer. Thus, the flavivirus glycoproteins are sufficient to induce particle budding.

Flavivirus assembly and budding

Virus-induced membrane structures called vesicle packets, which are continuous with the ER membrane, are the sites of flavivirus replication and assembly (Fig. 3). Within these structures the structural proteins are in intimate contact with the genome RNA. The C protein associates with the genome RNA via interactions between the positive charges distributed throughout the protein and the negatively charged phosphate backbone of the RNA. It is not yet clear how the C protein specifically recognizes the genome RNA; unlike for alphaviruses, a packaging signal has not been conclusively identified for flaviviruses. Coupling between genome replication and assembly within the vesicle packets has been proposed as a mechanism to ensure the specific encapsidation of the genome RNA. It has been shown that one or more nonstructural proteins (NS2A and NS3) are involved in genome packaging and NC assembly. The NC lacks a defined icosahedral structure as described above. Therefore, core formation is probably concomitant with the association of the C protein and RNA genome with the viral glycoproteins and budding into the ER lumen, thus giving rise to the immature particle (Fig. 3). The immature virion is transported from the ER to the Golgi where the viral glycoproteins are post-translationally modified. The cleavage of the prM protein in the trans-Golgi network triggers the dramatic reorganization of the viral glycoproteins that results in the formation of the mature virion (Fig. 3). The mature virion is then released from the host cell by exocytosis.

Conclusion

Following from the discussion of alphavirus and flavivirus assembly, it is apparent that the assembly of even the simplest enveloped viruses requires the complex interaction of viral and host factors in order to produce a virus particle which is at once stable and at the same time primed for disassembly. The whole range of the cell's machinery including the translation apparatus, polymerases, chaperones, and post-translational modification enzymes are co-opted by viruses in order to replicate the viral components necessary for assembly. Enveloped viruses have evolved to utilize different cellular membranes and cellular compartments for assembly and they take advantage of the secretory pathway to produce their viral glycoproteins. A majority of viruses bud from the plasma membrane (**Table 1**). This is the case with alphaviruses, where NC assembly occurs in the cytoplasm and the final assembly of the mature virion occurs at the plasma membrane. The high concentration of viral proteins, often concentrated at specific sites allows for the efficient interaction and assembly of virions. In contrast to alphaviruses, NC assembly and glycoprotein assembly is coupled in the flaviviruses and occurs in vesicle packets associated with the ER. Thus, the whole flavivirus virion is transported through the ER and Golgi while in the case of the alphaviruses only the glycoproteins are transported through the secretory pathway. These exit strategies are not unique and thus serve as model systems to study enveloped virus assembly and release.

Proteolytic cleavage of glycoproteins in order to convert them from stable oligomeric structures to metastable structures primed for fusion are common themes in enveloped virus structure and assembly. Cleavage of PE2 into E3 and E2 by a furin-like protease primes the alphavirus spike complex for fusion. A similar cleavage of prM triggers a dramatic conformational change of the flavivirus glycoproteins resulting in the formation of the mature virion which is now infectious.

Alphavirus budding requires the specific interaction of the NC with the E1–E2 spike complexes at the plasma membrane, thus ensuring that all virions have a genome packaged into them. However, the flaviviruses only require the interaction of the envelope proteins for budding, giving rise to subviral particles devoid of the C protein and genome RNA. Thus, the flavivirus envelope proteins alone are sufficient to drive budding of virus particles and the close coupling of genome replication and the C protein (perhaps mediated by replication proteins and host factors) is required to package the genome into virus particles. A third strategy for budding is exhibited by the retroviruses where capsid assembly has been shown to be sufficient to drive budding of the virus. In this case, targeting of the envelope proteins to these sites of CP assembly is essential to ensure the incorporation of the glycoproteins into the virion.

Although much has already been discovered about enveloped virus assembly, there are still many processes yet to be described. There is an increasing interest in the assembly pathway of viruses partly fueled by the potential to develop successful therapeutic agents targeting virus specific assembly processes. Advances in the field of structural biology will further help attempts to understand the assembly pathway of this important class of viruses.

Architecture of Viruses

Nonenveloped viruses have two essential components: protein and nucleic acid. The protein forms a coat called 'capsid' that packages the nucleic acid, which may be DNA or RNA. This complex constitutes a virion or a virus particle. The nucleic acid is the viral genome that encodes all the virus-specific genes required for viral replication. The protein capsid packages the viral genome during replication, and transmits it for the next round of infection. When the virion reaches the host cell, the capsid usually recognizes a specific receptor that helps the virion to enter. Once inside the host cell, the capsid has to release the viral genome so replication can begin. The size of a viral genome is usually limited, so only a few genes can be encoded. It is more efficient if only one or a small number of genes encode for capsid proteins that can self-assemble into a complete shell by use of many copies of the same proteins. The assembly of the capsid proteins follows a specific type of symmetry that allows a small protein unit to assemble into a large particle. The protein capsid can have a helical (filamentous virus) or icosahedral (spherical virus) symmetry. Helical symmetry is described by the diameter, d , the pitch, P , and the number of subunits per turn. There are as many capsid proteins as necessary for completely covering the nucleic acid genome. Icosahedral symmetry is defined by 12 fivefold axes, 20 threefold axes, and 30 twofold axes. A number, T , called the 'triangulation number', indicates how many quasi-symmetrical subunit interactions are within one asymmetrical region of the icosahedron. There are a total of 60 T copies of the capsid proteins in one icosahedral capsid.

For example, a picornavirus (pico-(small)-RNA virus) has a single positive-stranded RNA genome of about 8000 nucleotides. The RNA genome encodes a long polypeptide that is processed into individual viral proteins after translation directly from the positive RNA genome. Three of the 10 proteins are capsid proteins: viral protein 1 (VP1), viral protein 3 (VP3), and viral protein 0 (VP0). VP0 is processed to VP2 and VP4 after virus assembly. VP1, VP2, and VP3 are the three capsid proteins that form the body of the coat while VP4 is entirely inside the coat. There are 60 copies of each capsid protein in the coat. A picornavirus is, therefore, a $T = 1$ particle. However, the structure of VP1, VP2, and VP3 is highly homologous. If the small differences in each major capsid protein are ignored, the three proteins can be considered as the same building block. A picornavirus is thus called a pseudo- $T = 3$ particle (Fig. 1). The interactions between the capsid proteins in the coat are similar despite their different symmetry locations. For instance, VP1 (blue) interacts around the fivefold symmetry axis, whereas VP2 (green) and VP3 (red) interact with each other around the threefold symmetry axis. Since VP2 and VP3 are similar, the symmetry around the threefold axis is like a sixfold symmetry axis. This symmetry axis is therefore called a quasi-sixfold axis. The interactions between the neighboring VP1 proteins are considered quasi-equivalent (means more or less similar) to the interactions between VP2 and VP3 even though VP1 subunits are around a fivefold axis, and VP2/VP3 subunits are around a quasi-sixfold axis. This quasi-equivalence allows the closed capsid to be assembled using the same building block, the capsid proteins. It should be emphasized, however, that the true differences that exist in the capsid proteins are critically correlated with functions such as virus entry and release or packaging the viral genome.

Methods of Structure Determination

X-ray diffraction is the common technique used for studying the atomic structure of proteins and nucleic acids. When X-rays strike on the electrons of the atoms in a stationary specimen, a diffraction pattern of spots with different intensities is generated and recorded. By analysis of the diffraction pattern and the spot intensities, a three-dimensional electron density map (EDM) can be calculated by Fourier transformation. A three-dimensional chemical structure could be built based on the interpretation of the EDM. Two types of X-ray diffraction experiments are useful for virus structure studies: fiber diffraction (for filamentous viruses) and crystallography (for spherical viruses and globular viral proteins).

Another common technique is electron microscopy. Recent advances in electron microscopy allow researchers to determine relatively high-resolution three-dimensional structures of viral particles by use of image reconstruction of cryo-electron micrographs and electron tomography. This technique is particularly suitable for large viral particles that are difficult to crystallize. Electron microscopy and X-ray crystallography are therefore complementary to each other.

Atomic Structure of Helical Viruses

The disk of the tobacco mosaic virus (TMV) coat protein has been crystallized and its atomic structure resolved by X-ray crystallography. The intact TMV structure containing its nucleic acid could only be determined by X-ray fiber diffraction

Fig. 1 The capsid of Theiler's murine encephalomyelitis virus (TMEV), a picornavirus. The triangle outlines one set of 60 copies of each capsid protein.

experiments, as also was that of Pf2 phage. The coat proteins of TMV and Pf2 contain mainly α -helices and the nucleic acid interacts with the coat protein by one base (Pf2) or three bases (TMV) per protein unit. The protein subunit is arranged in a super-helical structure coincident with a super-helical structure of the nucleic acid. The protein subunits form the outer layer of the helix to protect the nucleic acid from the environment. The nucleic acid is embedded between the protein layers that are stacked up in the spiral structure. The axis of the coat protein helix coincides with that of the nucleic acid. Since the symmetry of the super-helix puts no limit on the length of the helix, the virus particle can grow as long as the length of the nucleic acid genome; in this way all bases in the genome are covered by the coat protein. The coat proteins of TMV have many aggregation forms, depending on pH or ionic strength. In natural conditions, the TMV coat protein forms a disk with two layers of 17 protein subunits in each. The subunit of the TMV capsid protein contains four antiparallel α -helices with connecting long loops. Each protein subunit takes the shape of a shoe. When the disks of the capsid proteins are stacked, the RNA fits into the grooves formed by the protein subunits. The backbone of the RNA has charged interactions with the side chains of the amino acids while the bases of the RNA are accommodated by the hydrophobic space. The TMV RNA genome is inserted into the center of the coat protein disk to begin virus assembly. More and more disks are added to the top of the growing virus particle to pull the RNA through the center of the super-helix. The assembly is completed when the complete RNA is pulled into the virus particle. The coat protein of Pf2 has a different shape that contains an extended α -helix. The coat protein is added one by one to the DNA helix emerging from the bacterial membrane. The length of the α -helix is in the direction of the virus particle.

Atomic Structure of Spherical Viruses

Nonenveloped spherical viruses form large single crystals under proper conditions. Their atomic structure can be determined by X-ray crystallography with aid of fast computers and synchrotron X-ray sources. Since 1978, there are numerous atomic structures of viruses reported. Today, atomic structures have been determined for every major family of nonenveloped viruses, especially human pathogens.

Most capsid proteins of these viruses contain an antiparallel, eight-stranded β -barrel folding motif (Fig. 2). The motif has a wedge-shaped block with four β -strands (BIDG) on one side and another four (CHEF) on the other. There are also two conserved α -helices (A and B): one is between β C and β D, and the other between β E and β F. In animal viruses, there are large loops inserted between the β -strands. These loops form the surface features of individual viruses. The common presence of the β -barrel motif in viral capsid proteins is the result of structural requirements for capsid assembly. It also points to a common ancestor of different virus families.

A virus capsid may contain multiple copies of the β -barrel fold with the same amino acid sequence (such as $T = 3$ calicivirus or $T = 1$ canine parvovirus) or with different amino acid sequences (such as pseudo $T = 3$ picornavirus). In some cases, there are two β -barrel folds in a single polypeptide (such as adenovirus hexon). Capsid proteins of spherical viruses can have other motifs such as α -helices in reovirus and hepadnavirus.

Fig. 2 The β -barrel fold found in spherical viruses. The fold contains eight essential β -strands: BIDG on one side and CHEF on the other side. The figure was generated with rhinovirus 16 VP1 (PDB code 1AVM).

Nucleic Acid–Protein Interaction

The viral nucleic acid genome is always packaged inside the protein capsid. Positively charged patches formed by the side chains of arginines and lysines are found on the interior surface of the protein capsid. These positively charged areas are the preferred binding sites for the nucleotides. Usually the structure of the nucleic acid cannot be observed in a single-crystal X-ray diffraction experiment because of the random orientation of the icosahedral particles in the crystal. However, in rare cases, the nucleic acid might assume icosahedral symmetry by interacting with the protein capsid. Fragments of the complete genome assume the same conformation, although with different nucleotide sequences, at locations related by icosahedral symmetry. Such structures have been seen in bean pod mottle virus, tobacco mosaic virus, pariacoto virus and flock house virus (RNA viruses), and canine parvovirus (DNA virus). The bases are stacked either as an A-type RNA helix or form a coiled conformation to fit the interactions with the protein capsid. In the case of pariacoto virus, the RNA genome forms a cage that reassembles the icosahedral symmetry of the capsid (**Fig. 3**). These viruses readily form empty virus particles and have a hydrophobic pocket on the interior surface of the capsid. The nucleic acid generally interacts nonspecifically with the capsid protein.

Evolution

The highly conserved β barrel motif of the viral capsid protein indicates that many viruses must have evolved from a single origin. The unique three-dimensional structure of this motif is required for capsid assembly and it is generally conserved over a longer period of time than the amino acid sequence. The superposition of the capsid proteins from different viruses can be used to estimate the branch point in the evolutionary tree for each virus group. The structure alignment not only relates plant viruses to animal viruses, RNA viruses to DNA viruses, but also viruses to other proteins such as concanavalin A that has a similar fold and competes with poliovirus for its cellular receptor. The evolutionary relationship of these viruses is supported by amino acid sequence alignment of more conserved viral proteins such as the viral RNA polymerase. The structural similarities of the capsid proteins support the notion of a common evolutionary origin among nonenveloped viruses.

Assembly

The icosahedral capsid is assembled from smaller units made of several protein subunits. For picornaviruses, a protomeric unit is first formed with one copy of each polypeptide after translation. The termini of the subunits are intertwined with each other to hold the subunits together in the protomer. The protomers are then associated as pentamers which in turn form the complete icosahedral virion while encapsidating the viral RNA. In $T = 3$ or $T = 1$ plant RNA viruses, the pentamers are formed by dimers of the capsid proteins. In adenovirus and SV40, the capsid proteins form hexon units (three polypeptides, each has two

Fig. 3 The interior of the pariacoto virus capsid (green). The structured RNA genome is shown in red. The figure was generated with coordinates of pariacoto virus (PDB code 1F8V).

β -barrels) or pentamers before they assemble into an icosahedral shell. The nucleic acid could be packaged at different stages of assembly.

Host Receptor Recognition Site

Animal viruses have to recognize a specific host cellular receptor for entry during infection. Host receptor binding is the initial step of virus life cycle and could be an effective target for preventing virus infection. Based on the atomic structure of animal viruses, it was found that the receptor recognition site is located in an area surrounded by hyper-variable regions of the antigenic sites. Usually, the area is in a depression (called the 'canyon') on the viral surface that may be protected from recognition by host antibodies. This structural feature is, for instance, present in human rhinovirus (also known as the common cold virus), and the active site of influenza virus hemagglutinin (HA). The receptor-binding site on influenza virus HA does not have a deep depression, but it is surrounded by antigenic sites. The receptor-binding area on the surface of the viral capsid is conserved for recognition by the receptor, whereas the sites recognized by antibodies are distinct from the receptor-binding site and keep changing from strain to strain. By this mechanism, the virus can escape the host immune system by mutating the antibody epitopes, and at the same time maintain a constant receptor-binding site to continue its infection of the host cells. Evidence supports that this is a general mechanism that viruses use to evade the host immune defense.

Antigenic Sites

Antibodies are the first line of defense by the immune system against a viral infection. The epitopes combined with the neutralizing antibodies are mapped on a few isolated locations on the surface of viral proteins. The structure of human rhinovirus complexed with Fab fragments showed that the antibody makes contact with an area about 6 nm^2 and that the epitope spans different discontinuous polypeptides. Therefore, an effective vaccine usually needs to include a complete viral protein or a large fragment. The binding of the antibodies does not significantly change the structure of the antigen. The exact mechanism by which antibodies neutralize antigens is dependent upon the binding site and processes of the virus replication.

Antiviral Agents

Viral infectious diseases can be cured if an agent can be administered to stop viral infection. Such agents have been synthesized and shown to bind to the capsid of rhinovirus in the crystal structure. The compounds were inserted into the hydrophobic pocket

within the β -barrel of the major capsid protein VP1. Binding of the compounds stops uncoating of the virion and the receptor binding, which resulted in the failure of releasing the viral RNA into the cytoplasm. These compounds inhibit infections of several other RNA viruses and may be effective against other viruses after modification since the β -barrel structure exists in many viruses.

The most successful antiviral drugs are the HIV protease inhibitors which are developed based on the atomic structure of the protease. Through iterative cycles of computer modeling, chemical synthesis and structural studies of the protein-inhibitor complexes, a panel of clinical effective drugs has been brought to the market and has shown great benefits to patients. Inhibitors of influenza virus neuraminidase have also been developed by the same method and marketed as antiviral drugs.

Virion Assembly: From Small Picornaviruses (*Picornaviridae*) to Large Herpesviruses (*Herpesviridae*)

Ling Zhu, Nan Wang, and Xiangxi Wang, Institute of Biophysics, Chinese Academy of Sciences, Beijing, China

© 2021 Elsevier Ltd. All rights reserved.

Introduction

Viruses are infectious agents composed of proteins and a viral genome, and occasionally, other components, such as lipids and carbohydrates. Upon infecting a host cell, viruses are able to use their own components and the cellular machinery to produce copies of the viral genome and proteins, which then assemble into progeny viruses that can eventually infect other host cells. The assembly of the virion is an essential step in the viral life cycle and thus understanding the mechanisms underlying the assembly of the viral particles could facilitate identification of targets or opportunities for novel antiviral therapies. More recently, the process of assembly of viruses has come into sharp focus due to renewed interest in self-assembled structures and their applications. With regards to self-assembly, viruses are remarkably sophisticated biological machines. Therefore, insights obtained from the characterization of the mechanism of the processes of self-assembly can be harnessed for use in nano- and bio-technology-based industries. In fact, we are already beginning to see the application of this knowledge; for example, viral capsids have been successfully used for guiding the synthesis of inorganic and organic nanostructures and as vectors for gene therapies.

Viruses present remarkable differences in (1) size, ranging from nanometers to hundreds of nanometers; (2) morphology, including spherical icosahedral particle, cylindrical- or bullet-shaped helical particle and filament- or brick-shaped or irregular particle; (3) molecular composition; (4) structural organization; and (5) complexity (Fig. 1). The simplest nonenveloped virions are made up of just an oligomeric protein shell (capsid) that encapsidates the viral genome. The capsid itself contains only one or a few types of protein subunits [some examples are shown in Fig. 1]. As opposed to this, in some large virions, the particles not only contain the viral genome, but also proteins and/or other macromolecules, which may be organized in internal subassemblies. Furthermore, proteins and/or protein subassemblies like portals, tails, fibers, etc. with specific functions may be externally attached to the genome-containing capsid (head) (e.g., bacteriophage ϕ 29 in Fig. 1). Lastly, enveloped viruses present an additional layer of complexity, where the capsid is surrounded by a lipid bilayer (envelope) in which proteins are embedded [e.g., Japanese encephalitis virus (JEV), and human herpes simplex virus (HSV) in Fig. 1]. Some enveloped virions have an intricate multi-layered structure made up of lipid, protein and/or nucleoprotein structured layers [e.g., African swine fever virus (ASFV) in Fig. 1].

Although viral morphologies are structurally diverse, most viral capsids have either icosahedral or helical symmetry. Roughly half of all viruses are spherical, usually icosahedral. The focus of this review is the assembly of icosahedral viruses. The formation of a simple icosahedral capsid involves tens of copies of a single type of capsid protein (CP). However, most capsids have complex structures, which are formed by using hundreds or thousands of one or several different types of CPs that may adopt various conformations within the capsid. Adaptation to different hosts and microenvironments has led to many variations in the modes of assembly of viruses. Here, we provide a general overview of an icosahedral viral capsid assembly and comment on the features of the stability of the capsid.

Structural Principles in Icosahedral Capsid Assembly

Typical icosahedral capsids must be made up of exactly 60 identical structural elements in order to fulfill intrinsic geometric constraints. The simplest icosahedral capsids, e.g., parvoviruses, are indeed composed of 60 identical CP subunits with the same

Fig. 1 Some representative virus particles. Particles are reproduced at the same scale (indicated by the bar on the top left) to clearly show the size and morphology. From left to right and top to bottom: TMV (Tobacco mosaic virus, PDB accession: 2OM3), Phi29 (bacteriophage, EMDB accession: EMD-1420), AYVV (Ageratum yellow vein virus, EMDB accession: EMD-4174), MS2 (bacteriophage, PDB accession: 1ZDH), HAV (hepatitis A virus, PDB accession: 4QPI), JEV (Japanese encephalitis virus, PDB accession: 5WSN), SH1 (Haloarcula hispanica SH1 virus, PDB accession: 6QT9), HSV (herpes simplex virus type 2, PDB accession: 5ZAP), ASFV (African swine fever virus, EMDB accession: EMD-0815).

Fig. 2 Icosahedral capsids with different triangulation number. Top left, $T = 1$ (no quasi-equivalence) such as MVM (Minute virus of mice); middle left, $T = 3$, such as JEV; bottom left, $T = 16$, such as HSV; right, $T = 277$, such as ASFV.

conformation (Fig. 2). Similar geometric constraints dictate the assembly of larger icosahedral capsids. Larger viruses must be made by using multiples of 60 subunits of a single CP type that adopt slightly different or quasi-equivalent conformations. This theory on the rules of the assembly of icosahedral capsids was firstly proposed by Caspar and Klug in 1962. The Caspar and Klug theory explained how some multiples of 60 identical subunits can be arranged with similar or quasi-equivalent interactions, following the $T = h^2 + hk + k^2$ rule, where h and k are integers and T is called the triangulation number. Icosahedral capsids made up of identical subunits can be thought of as geometrically composed of pentameric and hexameric capsomers, in which subunits in one configuration participate in pentamers, while subunits in any of the other conformations shape into hexamers (Fig. 2). The capsids mentioned previously, formed by 60 identical CP subunits in the same conformation are defined as $T = 1$ with 12 pentameric capsomers and no hexameric capsomers (Fig. 2). The larger, $T = 3$ capsids, e.g., those of flaviviruses, are made up of $60 \times 3 = 180$ identical CP subunits, each adopting one of the three quasi-equivalent conformations during assembly such that these capsids can be regarded as composed of 12 pentameric capsomers and 20 hexameric capsomers. A special case is observed in the picornaviruses where the capsid is built from 60 copies of a fundamental subunit (the protomer) composed of three paralogous proteins (termed VP1, VP2, and VP3) and a small extended polypeptide (VP4, located inside) with $T=1$ (pseudo $T=3$) symmetry. Some complex capsids have higher T numbers, e.g., the $T=16$ capsids of herpesviruses and the $T=277$ capsid of the African swine fever virus (Figs. 1 and 2). Interestingly, not all icosahedral capsids adhere to the quasi-equivalence rules of Caspar and Klug. For example, the $T=7$ capsids of polyomaviruses are made from 72 CP pentamers instead of the 12 pentamers and 60 hexamers as proposed by the quasi-equivalence theory.

Although many viruses, such as parvoviruses, picornaviruses, polyomaviruses, and some large DNA viruses (ASFV and mimiviruses), are not related in amino acid sequences, the core of their major CPs fold into an eight antiparallel β -strands containing structure termed as the 'jelly roll' fold (Fig. 3). The structure of the CP subunit in some viruses; particularly in large DNA viruses, consists of two jelly roll domains. However, the single jelly roll structure is more common, as it also occurs in the CP subunits of small icosahedral viruses (Fig. 3). Except for the loops connecting the strands of the jelly roll, the overall topology of all the CP subunits is similar. The loops form the major epitopes and confer virus-specific differences. The remarkable similarity of these jelly rolls among viral CPs that do not share amino acid sequences and belong to different families of viruses, suggests a common ancestral evolutionary history.

Synthesis of Nascent Capsid Assembly and Assembly Intermediates

For successful assembly, the synthesis of the CPs is regulated for the following purposes: (1) synthesis quantity, the accumulation of high amounts of CPs in the host cells is necessarily required to compete with the vast amount and diversity of pre-existing cellular proteins; (2) synthesis speed, CPs synthesis must reach the maximum levels by the time the viral genome is being replicated, so that it can be efficiently packaged; and (3) synthesis stoichiometry, CPs must be synthesized in the proper ratio to ensure the correct assembly of viral particles.

Viral capsids are assembled from capsid building blocks (CBB). CBBs are built using either identical CPs or non-identical CPs that are related by two-fold, three-fold, and five-fold symmetry axes. The stable oligomeric CBBs may possibly act as assembly intermediates during the capsid assembly process and the regular interactions between the CBBs and their neighbors could probably facilitate the further assembly of the capsid. Results of experiments performed using in vitro assembly systems in combination with diverse theoretical approaches have shed light on the fundamental principles of viral capsid assembly starting from CBBs. Some studies also support a nucleation-driven cooperative process for capsid assembly, which begins with a lag phase during which a critical concentration of the CBB is built. This phase is followed by a build-up of an assembly line of intermediate structures. The contacts and structural changes in CBBs as well as assembly intermediates drive the assembly of viral capsids.

Fig. 3 Structures of representative CPs with single or double jelly roll fold domains are described here. Ribbon diagrams of the VP1 subunit in the MVM (PDB accession: 4ZPY), the VP1, VP2, and VP3 subunits in the hepatitis A virus (HAV, PDB accession: 4QPI), the VP1 subunit in the SV40 (PDB accession: 3BWQ), the major capsid proteins in AdV (adenovirus, PDB accession: 4V4U), ASFV (PDB accession: 6L2T), and PBCV-1 (Paramecium bursaria Chlorella virus 1, PDB accession: 6NCL). The jelly roll fold domain is colored in red, other regions are presented in yellow color. The figures are prepared using the Pymol program (<http://www.pymol.org>).

Modes of Assembly

Assembly of a viral capsid is a complex oligomerization process that involves a sophisticated pathway, which is regulated by ordered interactions between the CPs or CBBs. Three main modes of assembly for the viral capsids have been recognized. These are: (1) Self-assembly, where the CP subunits can spontaneously assemble themselves into capsids under appropriate conditions; (2) Scaffolding protein-assisted capsid assembly, where not only the CP subunits, but also the scaffolding proteins from viruses or host cells are required for the capsid assembly; (3) Viral genome-assisted capsid assembly, where specific and simultaneous

interactions between the CP subunits and the viral genome drive the capsid assembly. Details of each of the assembly modes with specific examples are described below.

Capsid Self-Assembly

Empty capsids of many icosahedral RNA viruses are known to exist during the viral life cycle or under specific conditions, such as those of the cowpea chlorotic mosaic virus (CCMV), which can aggregate into capsid-like particles at high ionic strength. The natural empty particles are produced in cells infected with some, but not all picornaviruses; weak protein-protein interactions are sufficient to drive assembly of Hepatitis B virus capsid. When properly isolated, these empty particles are antigenically indistinguishable from virions and can be completely dissociated into CBBs or CPs in vitro by treatment under special conditions. To some extent, the capsid self-assembly resembles the viral assembly. As a representative example, the capsid self-assembly for picornaviruses is summarized below.

The *Picornaviridae* are an important family of human and animal pathogens, including poliovirus (PV), human rhinovirus (HRV), enterovirus 71, hepatitis A virus, and foot and-mouth disease virus. The 30-nm-diameter virion comprises 60 copies of each of the structural proteins, VP1, VP2, VP3, and VP4, (VP1, VP3, and VP0 in empty particle, VP0 is the precursor of VP2 and VP4) arranged in a pseudo- $T = 3$ ($T = 1$) icosahedral lattice (Figs. 1 and 2). The viral genome is translated in a single open reading frame to produce a polyprotein that is cleaved co-translationally by viral proteases to yield the viral proteins. An early cleavage of the polyprotein releases a precursor protein P1, which is further processed by the viral 3CD protease into a heterotrimeric protomer (VP0–VP3–VP1), sedimenting at 5S (Fig. 4). It is believed that 5S protomers self-associate to form 14S particles (VP0–VP3–VP1)₅ and that 12 copies of 14S particles can self-assemble into an 75S empty capsid [(VP0–VP3–VP1)₅]₁₂ (Fig. 4). Given the fact that empty particles are generally stable enough under physiological conditions, it suggests that empty particles are not a storage form of 14S particles, at least for some enteroviruses (Fig. 4). However, it has still been debatable whether empty particles are either a dead-end product or direct precursor into which viral RNA is packaged by as-yet-unidentified machinery. Regardless, the encapsidation appears to be tightly linked to RNA replication, as in vitro assembly assays reveal an absolute dependence of encapsidation on *de novo* synthesis of progeny RNA. Encapsidation leads to the formation of the provirion, which consists of the RNA and 60 copies each of VP0, VP1, and VP3. The maturation of the provirion is signaled with the cleavage process of VP0 into VP2 and VP4 by viral RNA, which significantly increases the stability of the particle; albeit, the detailed mechanism of VP0 cleavage remains elusive. Viral genome-assisted capsid assembly in picornaviruses will be discussed further in the following paragraphs.

Scaffolding Protein-Assisted Capsid Assembly

The correct assembly of many icosahedral viral capsids requires assistance of scaffolding proteins. This requirement of scaffolding proteins has been observed in dsDNA bacteriophages, herpesviruses, and some ssDNA phages. Typically scaffolding proteins taking part in some steps of the assembly process by establishing specific but transient protein-protein interactions with the CP subunits are later digested away during virus maturation, being absent in the mature virion. Some viruses encode only one type of scaffolding protein. This protein acts as an assembly chaperone, forming an internal scaffolding core in the procapsid. Other viruses encode more than one scaffolding protein, forming both the external and internal scaffold to drive the capsid assembly. In some viruses, the scaffolding proteins alone are capable of clustering together to form a scaffold core, that is subsequently used as a nucleus for capsid assembly by recruiting CP subunits. However, the scaffolding proteins interact with CP subunits in a co-assembly mode in which the scaffolding proteins facilitate CP subunits' associations and in turn the CP subunits promote the scaffolding proteins interactions by triggering conformational changes in them. As a typical example, the scaffolding protein-assisted capsid assembly for herpesviruses is described below.

Herpesviridae are a large family of dsDNA viruses that cause a number of diseases such as encephalitis, oral and genital blisters, congenital disorders and even cancer, and whose members include herpes simplex virus (HSV), human cytomegalovirus (HCMV), Epstein–Barr virus (EBV), and Kaposi sarcoma herpesvirus (KSHV). The herpesvirus capsid initially assembles as a precursor procapsid that subsequently matures during DNA packaging facilitated through a portal channel. To form a herpesvirus precursor capsid, at least four types of components are required: VP5, triplex, scaffold, and portal complex, in which the portal assembles a unique dodecamer at a five-fold vertex. Scaffold proteins are reported to trigger the portal oligomerization and incorporation, determining the correct curvature and ultimate closure of the capsid shell. The recently reported high-resolution structure of HSV-2 capsid reveals a pronounced assembly pattern for triplexes, exhibiting a twofold symmetry organization pattern, on the capsid shell, together with a structurally rigid unit comprising a triplex and its covalently linked lasso triangle (probably function as a basic assembly unit), indicative of the possibility of triplexes acting as external scaffold proteins to regulate the correct assembly. Based on our more recent asymmetrical reconstructions of the HSV portal vertex (unpublished data), we propose that the formation of a unique “portal complex” with the requisite scaffold proteins, triplexes and VP5 is probably the first event for initiating proper precursor capsid assembly (Fig. 5). Subsequent assembly proceeds by the addition of assembly units to form the portal vertex. We envisage that five assembly units cluster to make up a “penton complex”, followed by the formation of the penton vertex by addition of assembly units (Fig. 5). With the mediation of the scaffold core and triplexes, eleven penton vertices are attached to the nucleation of the portal vertex, leading to a complete precursor capsid. After that, the cleavage of the scaffold

Fig. 4 Proposed model for poliovirus assembly. During the virus life cycle, viral translation produces a long polyprotein that is processed by viral proteases. Assembly of the virus is linked to processing of the polyprotein and proceeds through a series of assembly intermediates, including protomer, pentamer, natural empty particle, provirion and mature virion.

Fig. 5 Proposed model for herpesvirus capsid assembly. Herpesvirus capsid assembly starts from an assembly pool containing VP5, scaffolding proteins, triplexes (two copies of VP23 and a VP19C), and UL6. Three copies of VP5 and a triplex could form a triangular complex as an assembly unit. Scaffolding proteins trigger 12 UL6 to make up a dodecameric portal and associate with the portal, together with VP5 and triplexes, forming the portal complex. After this, the assembly units probably bind to the portal complex for assembling the portal vertex. Meanwhile, 5 assembly units could self-assemble into a penton complex, which recruits more assembly units to form the penton vertex. As soon as the formation of the two types of vertices is completed, 11 penton vertices and 20 free assembly units (Tf) attach to the portal vertex to form a precursor capsid in which the scaffold core formed by scaffolding protein ensures the correct curvature. The precursor capsid matures via a major structural transformation triggered by limited proteolysis of the scaffolding proteins. Angularization might make the capsid expose the VP26 binding site. The angularized capsid encounters the terminase complex and dsDNA is packaged into the shell, after which the portal changes its configuration to disassociate from the terminase and the CVSC are attached to the vertices to form a mature capsid.

proteins causes the precursor capsid to undergo substantial conformational rearrangement such that the outer shell changes from roughly spherical to icosahedral. On conditions that the packaging machinery (terminase complex) is engaged properly, DNA is pumped into the angularized shell. Then, newly packaged DNA triggers the portal conformational switch from an immature to a mature state, recruiting the CVSC and ensuring the retention of DNA, resulting in the formation of C-capsids (Fig. 5).

Viral Genome-Assisted Capsid Assembly

Encapsidation of the viral genome leading to the assembly of infectious progeny virions is an essential step in the life cycle of viruses. The most commonly employed strategies for packaging viral genomes involve either filling a preformed procapsid assembled via self-assembly or by assistance from scaffolding proteins with progeny genome or by nucleation of capsid assembly around viral nucleic acids (viral genome-assisted capsid assembly). We have a convincing picture of how some bacteriophages and herpesviruses package their dsDNA genome into a preassembled procapsid. This process involves an ATP-driven packaging motor complex and a portal complex located at one of the vertices of the icosahedral capsid (see the section of scaffolding protein-assisted capsid assembly). However, many other viruses, in particular ssRNA viruses, package their genome concomitantly with capsid assembly, in which the viral genome plays key roles in recruiting CPs or CBBs by charge interactions, yielding genome-containing virions. In these cases, no natural empty particles are produced during the virus life cycle. The process of viral genome-assisted capsid assembly is reviewed next, by focusing on some well-studied examples.

For many ssRNA icosahedral viruses, the initiation of virion assembly involves the recognition of a specific nucleotide sequence in the viral genome called the packaging signal by CP subunits. The length, stiffness, and the secondary structure of the viral RNA play essential roles in determining capsid morphology and assembly efficiency. Even in the absence of the viral RNA, the CP subunits of some single-stranded RNA viruses have abilities to self-assemble *in vitro*, but the assembly efficiency is much higher in the presence of genomic RNA; as observed in the cases of the assembly of bacteriophage MS2 and most picornaviruses. Structural and experimental evidences reveal that binding of the translational repressor (TR, a stem-loop in the viral RNA, known as a packaging signal) to the CP dimer triggers a conformational switch from the symmetric dimer, the dominant form in solution/cell cytoplasm, to its asymmetric configuration, constructing the capsid with a ratio of 1:2 (symmetric dimer: asymmetric dimer). Sequence-specific interaction between CP dimer and a 19 nt-length RNA stem-loop (TR) that has been well characterized is believed to function as an assembly initiation site *in vivo*, ensuring in this case cognate packaging of viral RNA even in the presence of competing RNA phases.

However, previous studies suggest that picornaviruses might be an exception to exploiting high affinity CP: RNA interactions for initiating virion assembly. Many studies including extensive nucleotide recoding of large sections of the polio genomes have failed to identify any RNA determinants involved in picornavirus assembly. Recently, multiple genome regions in parechoviruses, belonging to the family of *Picornaviridae*, have been reported to possess high affinity for CP subunits. Remarkably, these bindings of the genomic sequences to CPs are sequence-specific. Several high-resolution parechovirus structures (including Ljungan virus) have been reported that do contain 60 extensive densities for RNA fragments in close contact with the overlaying CPs, amounting to some 12% of the viral genome. These data support the existence of multiple RNA-based PSs in some of the picornaviruses and these PSs contribute differentially to assembly efficiency as expected for a PS-mediated process. Apart from PSs' mediation, there are also competing RNA conformations that regulate replication, translation and assembly. In line with this, in picornaviruses, the virally encoded 2C protein induces nascent viral RNAs with special local secondary structures into the pentameric CBBs ((VP0-VP3-VP1)₅). The above observations have led to a suggestive scenario for viral genome- assisted capsid assembly in many ssRNA viruses. In combination with the possible mediations led by viral encoded proteins and host cell factors, the binding of CP subunits to the viral RNA might trigger the structural changes of viral genome from an extended, secondary structures enriched fold to a highly compacted configuration. In turn, the folded RNA can facilitate CP polymerization and determine the size and geometry of the particle-to-be, ensuring the right assembly for virions.

Concluding Remarks

Studies on molecular mechanisms for viral capsid assembly are gaining more attention and importance, which also reflects how much we do not know yet about these processes. Recent dramatic improvements and new developments in structural, biophysical and biochemical techniques, and the discovery of novel theoretical and experimental approaches have provided impetus for a better understanding of these fundamental aspects of the viral assembly.

PS Packaging signal

Glossary

Adenosine 5'-triphosphate (ATP) The principal molecule for storing and transferring energy in cells.

ATP-driven genome packaging A genome packaging mechanism reliant on ATP to package the viral genome into a preformed capsid.

Energy-independent genome packaging A genome packaging mechanism reliant of a co-assembly mechanism in which genome packaging and virus assembly are

concomitant. It is known as “energy independent” as no external energy sources, such as ATP, are required for packaging.

Packaging signal Nucleotide sequence/structure element in a viral genome that directs the packaging of the viral genome.

Packaging signal mediated assembly An assembly mechanism reliant on the collective action of multiple dispersed packaging signals.

Introduction

Viruses employ a wide range of distinct genome packaging strategies that depend on both the sizes and chemical nature of their genomes. Smaller viruses typically assemble their nucleocapsids around their genomes in a co-assembly process combining genome compaction with capsid formation. Larger viruses, on the other hand, form empty capsids into which the viral genome is subsequently packaged, e.g., with the help of a packaging motor. Packaging strategies are adapted to the biophysical properties of the nucleic acids to be packaged, such as their persistence lengths, with smaller viruses favoring nucleic acids that are more compactable. We therefore organize this article by genome size ([Fig. 1](#)).

Energy-independent Genome Packaging in Small Single-Stranded Viruses

Positive-sense RNA virus genomes typically comprise three to ten genes, including the structural proteins and an RNA-dependent RNA polymerase (RdRp). Viruses with the shortest genomes, ranging from ~ 1 to ~ 3.5 kilobases (kbs) in length, are typically packaged into icosahedral capsid architectures formed from between 60 and 240 coat proteins (T -numbers in the range $T = 1$ to $T = 4$). Such viruses co-assemble their capsids around their genomes, and sequence/structure elements in the genomic RNA called packaging signals (PSs) are known to aid both genome compaction and capsid assembly ([Twarock and Stockley, 2019](#)). Well-studied examples of this genome packaging mechanism occur in satellite tobacco necrosis virus (STNV), that packages its ~ 1.3 kb-long genome into a $T = 1$ capsid formed from 60 coat proteins ([Fig. 2\(A\)](#)). It has been shown that the genome packaging mechanism in this virus relies both on a 5' assembly initiation cassette formed from five PSs, and multiple dispersed other PSs distributed along the entire genome ([Patel et al., 2015, 2017a](#)). Its packaging properties can be enhanced via variation of the PS sequences/structures. This implies that packaging properties can be engineered and controlled in a laboratory environment, and potentially harnessed for applications in nanotechnology and medicine.

Another example of PS-mediated genome packaging is bacteriophage MS2 ([Fig. 2\(B\)](#)). Its ~ 3.5 kb-long genome becomes packaged into a $T = 3$ capsid formed from 89 coat protein dimers, 29 symmetric and 60 asymmetric ones, and a single copy Maturation Protein that takes the place of one of the symmetric dimers (see [Fig. 2](#)). PSs have been identified in this virus using Hamiltonian Paths Analysis ([Twarock et al., 2018](#)), resulting in predictions that are in excellent agreement with experiment. The genome packaging mechanism can also involve other proteins. For example, in Picornaviruses packaging-signal mediated assembly occurs in the context of an assemblysome that also involves a non-structural protein in complex with the viral polymerase ([Shakeel et al., 2017](#)). It appears that PSs in these viruses are conserved across different strain variants ([Shakeel et al., 2017](#)). For Picornaviruses that undergo a maturation event, such as Rhinoviruses and Enteroviruses, there is more than one type of packaging signal ([Chandler-Bostock et al., 2020](#)), and it is possible that PSs act at different life-cycle stages.

In all cases discussed above, specific interactions between the viral genome and capsid protein form an integral part of the genome packaging mechanism, and are the common characteristic of the genome packaging mechanism. It is still debated how many other small viruses share this mechanism. For example, plant viruses like Cowpea Chlorotic Mottle virus (CCMV) package

Fig. 1 Overview of scale-dependent changes in genome packaging. Viruses with increasing genome sizes employ distinct genome packaging mechanisms. Whilst smaller viruses favor an energy-independent genome packaging mechanism, larger viruses use an ATP-driven motor to package their genomes into a preformed capsid. Virus structures have been rendered as a cartoon using UCSF Chimera based on PDB 1AYM (HRV16), 3J06 (TMV), 4BBL, 6QX8, 3LBW, 6Z5L, 6NHP, 1PD3, 5HUG (Influenza RNP, RdRp, M2, M1, HA, NEP, NA respectively), 1GC1 (HIV), 6VXX (CoV), 2XYZ (P22), 6CGR (HSV-1), 6HY0 ($\phi 6$), (6NCL (PBCV-1); and EMD-0300, EMD-0294, EMD-0295 and EMD-0296 ($\phi 6$ genome).

Fig. 2 Examples of an energy-independent co-assembly mechanism. Smaller viruses combine genome compaction and capsid assembly into a single step. This is facilitated by multiple dispersed sequence/structure motifs called packaging signals (PSs), that act collectively in a mechanism known as packaging signal-mediated assembly. (A) In Satellite Tobacco Necrosis Virus (STNV) PSs promote formation of CP complexes that become the particle 3-fold axes in the $T = 1$ capsid shell. (B) In bacteriophage MS2, PSs promote the switch from a symmetric to an asymmetric CP dimer, that is required around the 5-fold axes for particle formation. Virus structures have been rendered as a cartoon using UCSF Chimera based on PDB 4BCU (STNV), 1ZDH and 5TC1 (MS2).

one of three distinct genomic RNA segments into separate versions of the same type of capsid shell, which may suggest that packaging is non-specific. However, it is also possible that all three distinct segments present similar signals as a means of ensuring that all three are packaged with the required frequency. In any case, the assembly efficiency that PSs confer on the virus assembly process make it highly likely that this mechanism has evolved widely among small RNA viruses.

A similar mechanism is also employed by small DNA viruses that package their genomes in the form of pre-genomic, single-stranded RNA. An example is Hepatitis B Virus (HBV) (Patel *et al.*, 2017b), that packages its ~ 3.2 kb-long pre-genome into nucleocapsids with $T = 3$ or $T = 4$ capsid architectures. HBV is an example of a virus that undergoes a reverse transcription step following genome packaging, perhaps accounting for the fact that the number of PSs is typically smaller in these viruses than for ssRNA viruses, thus permitting the reverse transcription step to occur *in capsa*.

Nodaviruses are icosahedral viruses with ~ 4.5 kb genomes that are packaged into $T = 3$ capsids 29–35 nm in diameter. Examples are Pariacoto and Flockhouse virus. Packaging is achieved by a bipartite organization into a large (RNA1, ~ 3.1 kilobases in length) and small (RNA2, ~ 1.4 kilobases in length) segment. Whilst RNA1 encodes a protein with multiple functional domains, including a transmembrane domain and an RdRp domain, RNA2 encodes only a viral capsid protein precursor, which is auto-cleaved into two mature proteins during virus assembly. Roughly 35% of their single-stranded RNA genomes are organized into dodecahedral cages composed of RNA duplex, and there are extensive interactions between portions of the viral RNA genome and the icosahedral capsid, reminiscent of the packaging signal-mediated assembly mechanism.

Single-stranded RNA and DNA viruses with genomes of size ~ 6 kb appear to employ a different genome packaging mechanism. These viruses typically form helical structures around their genomes, resulting in rod-shaped capsid architectures. An example of a positive-sense single-stranded RNA virus is the Tobamovirus tobacco mosaic virus (TMV) that infects a wide range of plants. Its ~ 2 k coat protein subunits form two-layer disk structures that assemble around its ~ 6.4 kb long genomic RNA using the “lock-washer” mechanism, forming helical particles ~ 300 nm in length and ~ 18 nm in diameter. Genome packaging specificity is ensured by a single 69-nucleotide long packaging initiation signal, but there is no evidence for multiple dispersed signals in this virus.

Single-stranded DNA viruses of comparable length also form rod-shaped structures. An example is the ~ 6.4 kb long circular ssDNA of the filamentous bacteriophage M13. It is encapsidated by ~ 2.7 k coat proteins (the major protein P8), and this nucleoprotein rod becomes capped with five copies of different minor proteins. These are five copies of the surface exposed P9 and a more buried companion protein P7 at one end of the filament, and five copies of P3 and its less exposed accessory protein P6 at the other one. In contrast to the TMV case, the genome packaging mechanism is still poorly understood, but it is at least partially considered electrostatic.

Energy-independent Genome Packaging in Larger (ss)RNA Viruses

The flaviviridae, which have genomes between 9 and 12 kb in length, and the alphaviruses, with genomes 11–12 kbs long, are among the larger RNA viruses self-assembling into icosahedral capsids without an energy-driven mechanism. Both of these families contain

human pathogens of significant clinical interest. These viruses package their genomes within icosahedral capsids, but unlike RNA viruses with shorter genomes, they also surround their capsids with lipid bilayer envelopes. The longer genomes encode additional structural proteins to mediate this process, primarily envelope (E) proteins. However, flaviviridae also encode smaller membrane (M) proteins. Given the relatively small increase in genome length in comparison to the picornaviruses, it is perhaps expected that these viruses should share similar assembly and packaging mechanisms. The packaging of flaviviruses including dengue, Zika and Hepatitis C have been suggested to rely upon regulation of the viral genome, even though this has not been definitively verified (Mazeaud *et al.*, 2018). Cryo-electron microscopy (cryo-EM) reconstructions of Zika virus show ordered density of RNA seemingly in contact with the capsid surface, suggesting the presence of RNA-protein contacts, whilst Hepatitis C virus has been shown to use multiple-dispersed packaging signal motifs to ensure reliable, specific assembly, similar to picornaviruses.

Packaging of alphaviruses has been intensively studied in recent years, perhaps due to the growing spread of Chikungunya virus (Mendes and Kuhn, 2018). The alphavirus Venezuelan equine encephalitis virus (VEEV) was used in mutational studies of alphavirus assembly to identify a region of the genome required for efficient assembly. Reports suggest that their packaging signals take the form of 4–6 stem-loops containing a triple guanine motif at the start of the loop, and more than one stem-loop was shown to be required for efficient assembly. Phylogenetic analysis shows that this packaging signal is conserved across the majority of the alphaviruses. This single-site packaging signal was initially suggested as a contrast to the multiple-dispersed packaging signal paradigm, in part because this packaging signal is not a determinant of assembly, but does greatly improve the efficiency of assembly (Mendes and Kuhn, 2018). However, a recent study using the alphavirus Semliki Forest virus (SFV) identified multiple capsid protein binding sites dispersed across the genome, strongly suggesting that multiple-dispersed packaging signals play a role in genome recognition and packaging in this viral family.

With increasing genome size, the capsids required to package them must also increase in size. As larger capsids are less likely to form by diffusive aggregation of the protein subunits, even if facilitated by multiple-dispersed PSs, evolution has resulted in multiple strategies to ensure that viral genetic material is packaged specifically and efficiently. One solution to the genome packaging problem for larger viral genomes is its segmentation. Viruses in the family *Orthomyxoviridae*, for example, have negative-sense, single-stranded RNA genomes that are in between 10k and 14.6k nucleotides in length, and organized into six to eight segments. A prominent example is influenza A virus, with a 13.5 kilobase long genome distributed over eight segments. These present as ribonucleoproteins, each composed of a distinct RNA segment bound by the viral polymerase and oligomeric viral nucleoprotein (Bolte *et al.*, 2019). A specific organization of the segments, called the 1 + 7 configuration, is important for influenza A virus genome packaging. The morphology of *Orthomyxoviridae* is either ellipsoidal or filamentous, with particles 80–120 nm in diameter and up to 20 µm long. Viruses in this family face the challenge of ensuring the packaging of the correct number and types of segments. This is achieved via packaging sequences that are unique to individual segments in combination with specific nucleoproteins, and relies on a redundant and plastic network of RNA-RNA and potentially RNA-nucleoprotein interactions (Bolte *et al.*, 2019). A similar mechanism reliant on an interaction network of multiple RNA signals in the genome segments occurs also in other multi-segmented viruses, such as Bluetonguevirus (AlShaikhahmed *et al.*, 2018) (see below). Whilst it is widely accepted specific sequences within the viral RNA segments are required for genome packaging, many mechanistic details are to date not yet fully understood.

As genome size increases even further, so does also the diversity in capsid morphology when compared with smaller RNA viruses. A common strategy is to separate two of the roles of the capsid; genome compaction and genome packaging. In RNA viruses with longer genomes, the genome is often selectively bound by a protein called *nucleocapsid* (NC), which is distinct from the protein controlling the conformation of the virus particle and aids genome compaction. This approach is exemplified by the Ebolavirus, which has a negative-sense RNA genome of around ~19k nucleotides. The RNA is protected by multiple copies of NC, which bind to the genome via non-specific interactions. The protein-genome complex, or ribonucleoprotein (RNP), forms the core of the virion, while the envelope protein (among other proteins) forms the filamentous capsid along with cellular lipids. The same organization is seen also in the closely related Marburg virus, and the plant-infecting aspiroviridae whose genomes are ~11 kb long.

Retroviruses have shorter genomes, typically 7–10 kb in length, and the virus packages two copies of the genome into each virion. Whilst the evolutionary advantages of packaging two genome copies are still debated, they might be related to the high degrees of recombination in these viruses, and the mechanism favors packaging of two genome copies of similar type. Retroviruses have evolved a mechanism to ensure that precisely two copies of their genome are packaged. In human immunodeficiency virus (HIV) this is achieved via the dimerization initiation sequence, a palindromic sequence of six nucleotides which enables an inter-strand interaction to form between two genomes. Genome specificity is ensured using a mechanism similar to that in smaller RNA viruses, via a packaging signal sequence/structure motif encoded in the genomic RNA. In HIV, the most well-characterized retrovirus, this packaging signal is denoted as *Psi*, which is now widely assumed to be the stem-loop SL3 in the 5' leader of the genome. It specifically binds the nucleocapsid domain of the Group-specific antigen, or Gag protein. A GGAG motif in a tetraloop enables a sequence-specific interaction of the SL3 stem-loop with the zinc-knuckles of the NC domain of Gag. This interaction is often referenced as 'the' packaging signal of HIV. However, it is not clear that the SL3-NC interaction is sufficient to ensure packaging, especially given that the neighboring stem-loop, SL2, also has a very high affinity for NC. Subsequent experiments have determined that multiple copies of NC bind to the 5' leader of HIV, suggesting a similarity with the multiple PS sites in the genomes of smaller RNA viruses. Prior to assembly of the complete virion, Gag forms complexes on the surface of the membrane which will later become part of the virion. The interaction between the NC domain and the RNA ensures that the genomes are localized before packaging. It is unknown whether the RNA-Gag interaction occurs prior to dimerization, but it is logical to assume that genomes localized on the membrane surface are more likely to join together into a dimerized complex than

two genomes in solution (Rein, 2019). Following dimerization, Gag undergoes proteolytic cleavage into matrix (MA), capsid (CA) and nucleocapsid (NC) domains, where the RNA-bound NC forms an RNP, while the CA domain forms the conical, mature capsid enveloped by a lipid membrane containing MA.

The coronaviridae genomes are among the longest of all viral single-stranded RNA genomes, ranging between 26 and 31 kb in length. In order to achieve the compaction required for packing into the confines of the viral particles, these viruses again delegate the stages of genome recognition and virion formation to distinct viral proteins. The coronavirus family contains viruses of clinical relevance, most notably SARS-CoV 1 & 2, MERS, as well as the ‘common-cold’ causing HCoV-229E, HCoV-NL63, HCoV-OC43, and HCoV-HKU1. Experiments with murine hepatitis virus (MHV), a lineage A betacoronavirus, involving packaged and non-packaged defective interfering RNA identified a region essential for packaging roughly 20 kb from the 5′ end of the genome. Further studies refined this to a 190nt sequence, which forms an extended stem-loop with a repeating sequence-structure motif on the 3′ side of its stem. This stem-loop is frequently referred to as the coronavirus PS. During replication, the coronaviruses produce multiple subgenomic fragments, to act as templates for translation of the various protein components. However, the PS ensures selectivity of the full-length genome, as the PS is not present in these shorter RNA fragments. Phylogenetic analyses suggest that other coronavirus lineages and genera do not contain this PS, although similar sequences have been found at other sites in the genomes (Masters, 2019). Alphacoronaviruses, such as TGEV, have been suggested to have an alternative packaging motif consisting of multiple stem-loops in the 5′ leader. However, these have not been well characterized and it is unclear how these would avoid the issue of packaging subgenomic fragments, given that these contain the 5′ leader. While the MHV PS is understood to be required to ensure packaging selectivity, the RNA-protein interactions it mediates are not understood. Coronaviral RNA forms an RNP with the nucleocapsid (N) protein, but these contacts are dispersed across the genome. Several hypotheses have been suggested involving the membrane (M) protein, but it is still debated which mechanism is employed. Given the relative simplicity of the repeating motif in the PS, it is also possible that multiple RNA-protein contacts could occur (Masters, 2019).

Double-Stranded RNA Viruses

The vast majority of these viruses have multi-segmented genomes that share similarities in replication strategies. These genomes are encapsidated into a multi-shelled icosahedral capsid. The two most studied viral families (*Reo-* and *Cystoviridae*) have revealed evolutionary pathways with similar results despite differences in the replication process, thus creating a competent viral progeny which includes a complete genomic component (Borodavka *et al.*, 2018).

Members of the *Reoviridae* are characterized by encapsidating 9–12 (+)ssRNA genomic segments into a structurally unaltered innermost $T = 1$ core particle, built from 60 asymmetric dimers of a single CP. This core particle nucleates around larger and ordered RNA complexes made from those (+)ssRNA genomic segments as a consequence of previous assortment, which occurs in cytoplasmic inclusion bodies called viroplasm. In Bluetongue virus (BTV), efficient core assembly is produced when all of the 10 (+)ssRNA segments are included, as well as the viral RdRp and RNA capping enzyme (CAP), both located near the 5-fold vertices on the inner surface. Additionally, this packaging process has been shown to occur sequentially, and is mediated by a combination of specific (1) PSs localized close to both UTRs, and (2) segment assortment signals (SAS) promoting trans interactions between different segments (AlShaikhahmed *et al.*, 2018). Finally, when all of the required components are inside the container of the $T = 1$ particle, this acts as a scaffold to build a surrounding $T = 13$ capsid and an additional final outer triple layer. In Rotavirus, the third layer is lost during cell entry, and allows the double-layered particles (DLPs) to synthesize (+)ssRNAs. Assembly of this DLP is mediated by cooperative interactions of disordered N-terminal capsid shell protein (CSP) protruding domains with both the RdRp and (+)ssRNAs. RdRp has a high affinity for the 3′-terminus of rotavirus (+)ssRNAs and entails the specific packaging of only those segments that are bound to RdRp molecules, thus ensuring the consequent replication. In addition to this, each individual genome segment is associated with RdRp complex that will allow later transcription and exit of a unique type of (+)ssRNA through each of the 5-fold pores. Furthermore, the non-structural protein NSP2 has been found to have chaperone-like activities and to be involved in sequence-specific inter-molecular contacts during the assortment of the 11 (+)ssRNAs.

Viruses of the *Cystoviridae* family share the same multi-layered capsid architecture of the *Reoviridae*, and the (+)ssRNAs segments are also encapsidated into an inner $T = 1$ core where they will be subjected to dsRNA synthesis by the RdRp. However, in contrast to the *Reoviridae*, these (+)ssRNAs are actively translocated into pre-assembled cores or procapsids in a similar way to dsDNA viruses (see below). This family is well represented by the phage $\phi 6$, whose genome is based on three dsRNA segments termed Large (L), Medium (M) and Small (S). In the case of $\phi 6$, the procapsid consists of a dodecahedron with the presence of RNA helicase molecules located at its outer vertices and the RdRp facing the inner surface. In contrast to reoviruses, and because of the presence of a helicase that confers the ability to package the viral genome, $\phi 6$ RdRp is not involved in this function. Genome packaging is mediated by specific PSs present at the 5′ ends of the three (+)ssRNAs that form unique secondary structures. These are recognized close to the helicase, which allows packaging to occur in a 5′ to 3′ directionality and sequentially starting with the smallest segment. This first event starts a chain reaction of procapsid expansion coupled to exposition of new recognition sites for the other (+)ssRNAs. Once the procapsid is completely expanded because of the presence of all segments, RdRp produces new dsRNA molecules which adopt a single-spoiled genome organization similar to dsDNA viruses (Ilca *et al.*, 2019).

Infectious bursal disease virus (IBDV), a virus from the Birnaviridae family, constitutes a remarkable singularity within dsRNA viruses as it encompasses diverse features from the different viral groups. Particles contain a variable amount of their genome, organised into RNP complexes similar to those in (−)ssRNA viruses. As an exception to all other dsRNA viruses, the IBDV particle

Fig. 3 Example of an ATP-driven genome packaging mechanism. Larger viruses, in particular dsDNA viruses, form an empty capsid prior to packaging. Genome packaging is facilitated by an ATP-driven packaging motor through the portal as illustrated here for P22. Virus structures have been rendered as a cartoon using UCSF Chimera based on PDB 2XYY (procapsid), 2XYZ (mature capsid), 2GP8 (Scaffold Protein), 4DKW (large terminase protein), 3P9A (small terminase protein), 5JJ1 (portal protein procapsid), 5JJ3 (portal protein mature capsid), 2POH (needle protein), 1TYW (tailspike protein); and EMD-0304 (genome in mature virion).

is built from a single-shelled $T = 13$ capsid, which instead shares similarities with the CP of (+)ssRNA picornaviruses. Additionally, the assembly of this $T = 13$ capsid is produced via a procapsid composed of an internal transitory scaffold shell similar to dsDNA herpesvirus. Finally, although viral assembly remains uncertain in most of fungal dsRNA viruses (chryso-, partiti-, toti- and quadrvirus), some of them have a multipartite genome, thus encapsidating each of the distinct dsRNA segments that constitute the complete genome separately into different single-shelled $T = 1$ particles.

Energy-Driven Genome Packaging in Double-Stranded DNA and Giant Viruses

The most abundant morphologies among bacteriophages are tailed phages with icosahedral capsids known as “heads”. Packaging of the genome into these viruses occurs via an ATP-driven packaging motor (Rao and Feiss, 2015), that couples ATPase to DNA translocation and fills the head to near-crystalline density. The mechanism of such packaging motors has been dissected in many viruses. For example, a nucleotide-dependent DNA gripping mechanism has been described in bacteriophage T4, bacteriophage $\phi 29$, bacteriophage P22, and thermophilic bacteriophage P23-45. Packaging motors are very sophisticated, adapting DNA rotation and step size to preserve subunit coordination as the capsid fills (Fig. 3).

Whilst this mechanism has been studied predominantly in dsDNA phages, variants have also been reported in animal virus descendants. An example is herpesvirus, which retains the basic characteristics of the phage packaging mechanism described above. Its dsDNA genome is packaged into an icosahedral nucleocapsid, that is structurally similar to that of tailed bacteriophages in the order of Caudovirales. There also are double-stranded RNA viral motors (Guo and Lee, 2007) that share similar characteristics (see above).

Mimivirus is a nucleo-cytoplasmic large DNA virus (NCLDV). Like other complex giant viruses in this family, such as megavirus and pandoravirus, it employs a packaging mechanism that is distinct from the ones described above (Chelikani *et al.*, 2014), i.e., the energy-independent packaging mechanisms of the RNA and DNA viruses with smaller genomes (<20 kb), or the portal-terminase packaging systems of the larger viruses. The precise determinants of this mechanism are still under investigation.

Conclusion

Genome packaging is a vital stage in any viral life cycle. A better understanding of the mechanistic details of this process opens up novel avenues to prevent formation of viable virus particles. The packaging signals identified in smaller RNA and DNA viruses are examples of such novel therapeutic targets. A better understanding of packaging mechanisms also enables their exploitation in bionanotechnology, where viral capsids are repurposed for cargo delivery and storage.

Glossary

Aggresome Perinuclear inclusion body assembled around the microtubule organizing center (MTOC) and surrounded by a cage of vimentin where the cell encloses misfolded proteins. Some DNA viruses hijack this pathway to concentrate materials and build their factories.

Autophagy Mechanism for degradation and recycling of cellular components. Expendable constituents are isolated inside a double-membrane organelle known as autophagosome that later fuses with a lysosome where materials are degraded. Some RNA viruses induce and use components of this pathway for building their factories.

Correlative light and electron microscopy Group of methods that combine light and electron microscopy imaging of the same specimen. Light microscopy offers a large field of view and imaging the dynamics of living cells.

Particular cells with interesting features are selected for high resolution electron microscopy (EM). This approach is very useful to study the biogenesis of virus factories.

Replication organelle Membranous structure that harbors viral replication complexes inside the viral factory. It is usually made of single-membrane vesicles or spherules, double-membrane vesicles, multi-membraned vesicles, tubule-vesicular cubic membranes or planar oligomeric arrays.

Viral replication complex Macromolecular structure constituted by viral polymerases, other viral non-structural proteins and cell co-factors that makes multiple copies of the viral genome and transfers them to the assembly sites.

Virus factory or viral factory Intracellular compartment that contains the viral replication organelles and the sites for viral particle assembly and maturation.

Introduction

Viruses are obligate intracellular parasites. In the extracellular environment, viral particles exist as rather simple macromolecular entities made of protein shells also known as capsids, and/or membranes, also known as envelopes, that protect and transport the viral genome from cell to cell. It is only during the intracellular phase of their life that viruses synthesize distinct molecules and perform activities that are characteristic of living entities. One of these activities is the construction of a platform for genome replication and morphogenesis, also known as virus factory (VF). The central element of the factory is the replication organelle (RO) where the viral replication complexes (VRC) make multiple copies of the viral genome. In many cases, factories are made of remodeled cell membranes and contain functional compartments with specific roles in virus replication, assembly and egress. Other cell elements such as mitochondria and the cytoskeleton are often recruited to viral factories and make contacts with the RO. In most cases, the specific role of these contacts is not known. VFs can be rather big, with a diameter of several microns and occupy large intracellular regions. VFs are dynamic structures that maintain their communication with intracellular transport pathways to incorporate essential components and to facilitate the exit of newly formed viral particles (Fig. 1). Furthermore, VFs change over time with the assembly and disassembly of particular structures needed for specific steps of the virus life. In some cases, VFs or only the ROs are mobile compartments that move inside the infected cell, like in the case of the early ROs of Vaccinia Virus, Hepatitis C Virus, rotaviruses and the mouse hepatitis coronavirus. In the case of some plant viruses, ROs are transported from cell to cell through intercellular channels known as plasmodesmata.

To build their replication neo-organelles and factories, viruses make use of cellular materials and signaling pathways. The study of VFs and the way they hijack cellular pathways give also insight in the pathway itself. Researchers have identified two main pathways hijacked by viruses to build their factories: The aggresome formation for DNA viruses and autophagy for RNA viruses. Moreover, viruses manipulate lipid synthesis and flows to create membranes with particular lipid composition and biophysical properties that are ideal for the activation and efficient performance of the macromolecular complexes that work in viral genome replication and assembly.

Although present in many VFs, it is not known why and how mitochondria are recruited to viral factories. It has been proposed that mitochondria would provide the energy storage molecule adenosine triphosphate (ATP) necessary for virus replication, but direct evidence is lacking. Alternatively, viruses may need mitochondrial components such as particular proteins that incorporate into the replication organelles where they would enhance viral genome replication. Another possibility is that viruses recruit mitochondria around VFs to block the innate antiviral immunity response mediated by these organelles.

Methods to Study Virus Factories

The study of virus factories includes the characterization of their structure, biogenesis, functions, and evolution over time (Fig. 1). Virus factories were identified with light and electron microscopy imaging techniques. The first evidences of the existence of VFs

¹These authors contributed equally to this manuscript.

Fig. 1 Main components and functions of virus factories and methods for their characterization. Techniques for characterizing the structure, biogenesis and evolution of VFs are listed on the left, those for studying their functions are listed on the right.

came from studies of thin-sections of infected cells visualized by transmission electron microscopy (TEM). These images showed viral particles associated with macro-structures made of organelles that had been remodeled and transported to particular intracellular locations. Light microscopy (LM) then showed how viruses change the organization of whole infected cells to build their VFs. Nowadays, advances in fluorescent probes and LM methods are providing new insights into the biogenesis and functional architecture of VFs. Time-course assays combined with immunofluorescence and confocal microscopy provide a general view of the progression of infection. For these studies, cells at different times post-infection (tpi) are processed for immunolabeling with primary antibodies specific for viral proteins and secondary antibodies conjugated with fluorophores. When fluorescent viruses are available, real time, live cell microscopy shows an accurate view of all steps of the viral infection, including the early stages of VF assembly (**Fig. 2(a)–(c)**). Moreover, simultaneous labeling of cell compartments with specific markers allows the identification of particular organelles subverted by the virus and provides a dynamic view of their transformation during VF assembly.

For a detailed analysis of VFs and their components, the high resolution of transmission electron microscopy is needed. The size of most viruses is beyond the resolution limit of optical microscopy and EM provides the necessary resolution to study viruses and their VFs. The most common approach is the study of thin sections of virus-infected cells. These sections must be thin enough (~50–100 nm) for electrons to go through and generate a projection image in the TEM. With advances in sample preparation methods for TEM we are getting close to the visualization of the VF native-like structure. Cryo-preparation techniques such as high-pressure freezing followed by freeze-substitution or frozen-hydrated sections are some of the options to visualize VFs close to their natural state. In addition, ultrastructural imaging can be done either in two dimensions (2D) or three dimensions (3D). The images a TEM generates from a thin section are 2D projections of three-dimensional, much larger structures. In these projections, we can observe considerable details about the elements that build the factory (**Fig. 2(d)**) but the spatial information within the volume of the structure is lost. Different 3D imaging techniques for biological samples are now available. They are unveiling how

Fig. 2 Visualization of a viral factory by live cell imaging, 2D TEM and 3D TEM. (a, b, c) Snapshots from a live cell microscopy movie showing the biogenesis and evolution of a bunyavirus factory (VF). BHK-21 cells were infected with the fluorescent bunyavirus eGFP-Gc-BUNV and transferred to a TCS-SP5 microscope (Leica Microsystems). Images were recorded every 15 min from 1 to 18 h post-infection (hpi). (a) Initial stage of factory assembly. (b) The viral factory grows over time with perinuclear localization. (c) Late stage of infection with the large factory and some secretory vesicles (arrows) with viruses at the plasma membrane. (d) Ultrathin section of viral factories observed after conventional embedding and TEM. BHK-21 cells were adsorbed with bunyavirus and fixed at 10 hpi; Golgi stacks and replication organelles (RO) that contain the replication complexes are shown with mitochondria and endoplasmic reticulum (ER) membranes surrounding the factories. (e) Factory as visualized by TEM of serial sections, 3D reconstruction and image processing. Vero cells were adsorbed with bunyavirus for 10 h. The modified Golgi stack (gold) with spherules/ROs (white) and newly formed viral particles (blue) is surrounded by mitochondria (red) and ER (brown), adjacent to the nuclear envelope (orange). Scale bars = 10 μ m in (a, b, c); 500 nm in (d); and 200 nm in (e).

different elements compose the VF macro-structure inside cells. Methods such as 3D reconstruction of serial sections (Fig. 2(e)) and electron tomography (ET) are currently applied to study the three-dimensional architecture of viral factories. 3D studies of VFs discovered inter-organelle contacts that do not exist in non-infected cells.

The group of techniques known as correlative light and electron microscopy (CLEM) combines both types of microscopy and allows the selection of particular cells with interesting features detected by (live) light microscopy imaging to study them at higher resolution by TEM. This strategy is very useful to study the different steps of the infection, such as the assembly of the VF and the heterogeneous response of different cells to the virus.

Microscopy studies show when, where and how the VF is built and therefore provide useful information about the most adequate tpi for other studies, such as the quantification of viral genome synthesis with real-time polymerase chain reaction (RT-PCR), viral protein production by western-blot and the production of intracellular and extracellular infectious viruses with titration assays. All these methods work together to identify VF functions in the infected cell. However, to assign particular activities to VF sub-compartments, an *in situ* molecular mapping of the structures is necessary. Detection of viral and cellular macromolecular complexes in VFs can be done with fluorescent probes and super-resolution light microscopy techniques. Stimulation emission depletion (STED), stochastic optical reconstruction (STORM) and total internal reflection fluorescence (TIRF) microscopy are some of these techniques that produce images at higher resolution than the one imposed by the diffraction limit. Their application in virology is still limited but they have a great potential to study the macromolecular architecture of VFs. At the ultrastructural level, molecular mapping is done with specific primary antibodies and secondary antibodies conjugated with colloidal gold particles in immunogold labeling assays. Recently, clonable tags for EM have been developed. The method known as metal-tagging TEM (METTEM) uses the metal-binding protein metallothionein (MT) coupled with a gold nano-cluster as an electron-dense tag. MT has unveiled the 3D organization of the Tombusvirus polymerase molecules in ROs and the movement of newly synthesized influenza virus ribonucleoproteins from factories to the plasma membrane before viral particle assembly and egress.

To identify the active ROs in infected cells, we count with assays of brome-uridine or brome-deoxyuridine incorporation for RNA or DNA viruses, respectively. These assays can be combined with immunofluorescence and confocal microscopy or immunogold labeling and electron microscopy to localize the sites where the viral polymerases are making new copies of the viral genome. In addition, probes for imaging specific viral RNA molecules are powerful tools to study viral replication and assembly in live cells. For example, fluorescence in situ hybridization (FISH) shows where the viral genome localizes and assembles to form new viral particles. Live FISH is a new technique under development. Never used for VF studies, it might show a dynamic view of viral genome synthesis, transport and assembly in virions.

A very active field of research is the identification of cell factors used by viruses to remodel compartments and build their factories. Gene expression microarrays can give us some clues by showing the genes that are over- or under-expressed in infected cells. Also, because viral non-structural (NS) proteins are usually involved in the biogenesis of ROs and VFs, techniques that detect protein-protein interactions such as yeast two-hybrid (Y2H), co-immunoprecipitation and proximity-dependent biotin identification (Bio-ID) followed by proteomics can catch relevant cell factors that interact with NS viral proteins early in infection. Validation of candidates can be laborious and involves methods such as gene silencing with small interference RNA (siRNA) or gene deletion using the CRISPR-Cas9 technology. Transient expression of viral and cell proteins after transfection with plasmids together with the generation of stable cell lines to control the expression of specific (tagged)-proteins are very useful techniques for these studies. The impact of the over-expression or elimination of the selected candidates in VF assembly and function is analyzed with the morphological and functional studies of VFs described above. When a fluorescent virus is available, another strategy is possible. Cells are infected with the recombinant fluorescent virus and at different tpi fluorescent and non-fluorescent cells are separated by cell sorting. Different cell populations can be then studied by EM, Proteomics, Transcriptomics, and Lipidomics to search for cell factors participating in viral infection in general and VF biogenesis in particular.

Representative Examples of Virus Factories

With the examples of selected DNA and RNA viruses, this section revises some typical viral factories. Most currently known DNA viruses carry out replication and transcription either entirely or partially within the nucleus of the host cell. For these viruses, the nucleus provides the machinery required for particular steps of the viral life cycle. Due to the limited comprehension of the functional architecture of the cell nucleus, the organization of nuclear factories is poorly understood.

Some of the best studied nuclear VFs are the ones of Polyomaviruses (PyV). PyVs are small, non-enveloped DNA viruses that infect mammals and birds. They have also been associated with the development of cancers in their hosts. During PyV infection, viral DNA and capsid proteins concentrate in nuclear bodies, suggesting that these sites may function as virus factories. However, PyV active DNA replication has been located adjacent to these bodies, associated with the recruitment of cellular factors such as DNA repair-related proteins. By electron microscopy and electron tomography, PyV factories are seen as collections of proteinaceous tubular structures and clusters of viruses. The current model proposes that PyV assembles from the ends of these tubules by a budding process and that nuclear bodies may provide the necessary architectural foundation for PyV tubular structures.

Some DNA viruses use also the cytosol for some steps of their life cycle. This is the case of herpesvirus, which causes many different diseases and is associated with human tumors. After entering cells, viral particles are transported to the nuclear envelope and the viral DNA is injected into the nucleus. Viral DNA replication, protein expression and core assembly occur inside nuclear factories. Then, immature viral cores exit the nucleus and enter the *trans*-Golgi network (TGN), where they acquire their final envelope. Thus, herpesvirus needs the cytosol and Golgi complex to complete the maturation of the virus progeny.

In contrast to most DNA viruses, the infection cycles of poxvirus and mimivirus take place exclusively within the host cytoplasm. Poxviruses such as vaccinia virus (VACV), are large, enveloped DNA viruses that infect vertebrate and invertebrate species. VACV replication requires rearrangement of vimentin filaments to build a vimentin cage, structure that assembles close to the microtubule organizing center (MTOC) and resembles the cellular aggresome. Before the formation of an aggresome-like structure, VACV factories are made of ER-derived membranes that build a mini-nucleus where viral genome replication takes place. Thus, VACV assembles two different factories, the first one is a mini-nucleus for viral genome replication and the second one is an aggresome-like compartment for viral morphogenesis.

Unlike DNA viruses, almost all RNA viruses form factories exclusively in the cytoplasm. These factories are in tight association with host membranes and depending on the virus, they use different cell organelles. Flaviviruses such as hepatitis C virus (HCV), dengue virus (DENV), or Zika virus (ZIKV) are positive-sense RNA viruses and important human pathogens. HCV is the major causative agent of chronic liver disease leading to cirrhosis and cancer. Early in infection, HCV induces a remodeling of ER membranes forming double-membraned vesicles (DMVs), and later on, it induces the formation of multi-membraned vesicles (MMVs) that are composed of several concentric membrane bilayers and accumulate at late tpi. These membranous rearrangements are produced by the action of viral nonstructural proteins. Viral RNA replication seems to be associated with DMVs which constitute the major component of HCV factories. DENV, the causative agent of dengue fever, is another flavivirus that induces rearrangements of ER membranes. EM has shown ER-derived structures with distinct morphologies: convoluted membranes (CMs) and vesicle packets (VPs). Using ET, it was demonstrated that these structures form part of a single ER-derived network. Furthermore, ET has allowed the study of the 3D architecture of DENV-induced ER membrane arrangements, revealing vesicles with pores that could enable the release of newly synthesized viral RNA. In addition, these studies showed the DENV particles budding into ER membranes, directly joined to vesicle pores. ZIKV is an emerging flavivirus that has been linked to abortion and birth defects associated

with severe infection of the central nervous system (CNS). Like other flaviviruses, ZIKV induces rearrangements of the ER forming characteristic vesicles and other membranous structures where viral replication and particle assembly occur in a coordinated manner. In addition, newly synthesized viral particles aggregate forming arrays of viruses in the lumen of the ER.

Coronaviruses (CoV) and arteriviruses are also positive-sense RNA viruses that generate membrane alterations in the host cytoplasm. There are common features between their virus factories, despite the significant differences in their morphology. The CoV group includes important human pathogens such as the severe acute respiratory syndrome (SARS) viruses. ET was decisive to reveal that coronaviruses form a unique reticulovesicular membrane network from the ER, where viral replicase subunits and double-stranded RNA (dsRNA), a viral replication intermediate, are both located. The membranous platform is continuous with the rough ER and contains in its lumen numerous vesicles that strongly stain for anti-dsRNA antibody. VP and CM structures have been also detected in association with the ER network. Equine arteritis virus (EAV) is the prototype of the family *Arteriviridae*, which includes important pathogens of animals. Arteriviruses also modify ER membranes, forming a network characterized by the accumulation of double-membraned sheets and DMVs. The diameter of these DMVs is smaller compared to those induced by CoV, and CMs are not observed. In addition, ET has shown that DMVs associate with each other in the membranous web. All these studies show that flaviviruses, coronaviruses and arteriviruses induce a single ER-derived endomembrane platform where viral replication and assembly are interconnected.

Many positive-sense RNA viruses replicate in single membrane invaginations named spherules that assemble in a variety of cell organelles. For example, togaviruses assemble spherules in lysosomes. The *Togaviridae* family is composed of two genera which include important animal and human pathogens, such as the Semliki Forest virus (SFV) and rubella virus (RUBV). Togavirus spherules are first formed at the plasma membrane, internalized by endocytosis and finally fused with late endosomes and lysosomes. These modified lysosomes, called cytopathic vacuoles (CPVs), are the central element of the VF that harbors viral replication and morphogenesis. Mitochondria and ER are recruited around the CPVs. In the case of RUBV, the Golgi complex is also recruited and participates in virus morphogenesis.

Other viruses assemble spherules in the ER, the Golgi complex, mitochondria, chloroplasts or peroxisomes. For example, the nodavirus Flock House virus (FHV), which can replicate in insect, plant, mammalian and yeast cells, assembles spherules in mitochondria. ET and 3D visualization have shown that spherules form by invaginations of the outer mitochondrial membrane and communicate with the cytoplasm through a "neck". Tombusviruses that are frequently used as a model to study virus-host interactions, assemble their spherules in the peroxisomes of plant and yeast cells. With advanced EM techniques, it was demonstrated that a cellular protein, the ESCRT (endosomal sorting complexes required for transport) component Vps4 controls the traffic of macromolecules between the spherule and the cytosol.

Negative-sense RNA viruses also build replication factories although their structure and biogenesis are less characterized. Bunyaviruses are an exception because their large VF has been studied in detail by light and electron microscopy. Bunyaviruses constituted a large order of enveloped viruses that includes emerging pathogens of humans, animals and plants. Bunyavirus factories use the Golgi complex, where the ROs are formed and consist of typical spherules connected with atypical cylindrical structures, surrounded by mitochondria and ER membranes. Viral replication takes place in spherules but the role of the cylinders is not understood. Serial sectioning and 3D reconstruction have shown the interactions between the different elements of this complex factory. The analysis of volumes together with immunogold labeling and TEM, suggested that the cylindrical structures probably mediate the transport of essential viral and cell factors throughout the factory. The virus assembly sites locate near spherules with VRCs. Viral particles bud in *cis*-Golgi membranes and mature in the *trans*-Golgi and *trans*-Golgi network (TGN) subcompartments.

From the examples described in this section, we can conclude that the ER that is the largest organelle in eukaryotic cells, is also the favorite compartment for viruses to build the VFs. One of the most spectacular viral-induced ER remodeling is triggered by the human reovirus. This dsRNA virus causes disease in children and young mammals, has been involved in the etiology of the celiac disease and is currently being used as an oncolytic in anti-cancer therapies. The human reovirus uses the ER to build their VFs also known as viral inclusions. To that purpose, two non-structural viral proteins, σ NS and μ NS bind to the peripheral ER elements and fragment them to make a collection of small membranous tubules and vesicles that aggregate and remain attached to the ER framework. These groups of membranes concentrate and protect the viral core-associated replication complexes and possibly provide also physical support for viral particle assembly.

Viral Factories as Targets for Antiviral Therapies

Emerging and re-emerging viruses constitute a serious public health problem and the need for new broad-spectrum antivirals is a top priority. Generally, antiviral drug development has focused on targeting specific viral components or on the modulation of the host immune response. Other strategies aim to develop molecules that target host cellular factors needed for viral replication. In this case emergence of resistant viruses is less likely. Moreover, the approaches focused on host cellular pathways used by viruses can favor the development of broad spectrum antivirals. Because different viruses use the same cell compartments and signaling pathways to build their factories, the identification of factors involved in VF biogenesis can provide new ways for antiviral design. For example, molecules targeting lipid transfer proteins (LTPs), enzymes of lipid metabolism, organelle remodeling proteins, and those involved in intracellular transport are good candidates for antiviral therapies. In addition, the current strategy known as drug repurposing is an attractive way to save time by finding molecules already approved to treat other diseases and use them to treat viral infections.

Glossary

IM Cytoplasmic membrane or inner membrane.

i-spanin The inner membrane spanin subunit. A type-II integral membrane protein (N-in, C-out topology). Forms a complex with the o-spanin that spans the periplasmic space. Both subunits are required for outer membrane disruption during lysis.

lipobox The lipobox is a four aa sequence at the C-terminus of SPII signal sequences. The consensus structure is {L, V, I}-X-{G, A, S}-C, where X is any aa except Pro or a charged residue. In *E. coli*, after secretion of the lipoprotein, the Cys residue of the lipobox is lipoylated by Lgt, before SPII cleavage and by Lnt, after SPII cleavage, resulting in attachment of the lipoprotein to the outer leaflet of the IM. If the residue following Cys is any residue but Asp, the fully-lipoylated mature lipoprotein is sorted by the LOL system to the inner leaflet of the OM.

MGL Multi-gene lysis. These systems feature two components (holins and endolysins) to lyse Gram-positive bacteria. Gram-negative bacteria require three components: holins, endolysins, and spanins for disruption of the IM, PG, and OM, respectively.

OM Outer membrane.

OMM Outer mycolate membrane.

o-spanin The outer membrane spanin subunit. A lipoprotein anchored in the inner leaflet of the outer membrane.

PG Peptidoglycan.

SAR endolysins Signal anchor release endolysins.

Accumulates as an IM protein with a single TMD and an N-in, C-out topology. Unlike a typical TMD, the SAR domain is rich in glycine and alanine. SAR endolysins are inactive until the SAR domain exits the bilayer. This occurs when the membrane is depolarized or can occur spontaneously at a low rate.

SGL Single gene lysis.

SPI The product of the *lep* gene in *E. coli*, Signal Peptidase I is the enzyme that cleaves the common secretory signal for periplasmic and outer membrane proteins after export through the Sec or Tat systems. SPI signal sequences are very diverse but have a common domain structure, including a basic N domain, a hydrophobic H domain and a hydrophilic domain of 3–7 aa, leading up to the cleavage site.

SPII The product of the *lsp* gene in *E. coli*, Signal Peptidase II (Lsp) is an enzyme involved in the processing of lipoprotein precursors. SPII signals resemble SPI signals except that the former ends in a lipobox motif (see below). SPII cleaves at the terminal Cys residue of the lipobox, so all mature lipoproteins have an N-terminal Cys residue.

TMD Transmembrane domain.

u-spanin A unimolecular spanin. In contrast to the two-component spanin systems, which use both an i-spanin and an o-spanin, the u-spanin is a single peptide with a lipoprotein OM anchor and a C-terminal transmembrane domain. U-spanins disrupt the outer membrane during lysis.

Introduction

Viruses of prokaryotic cells generally face two problems in achieving release from the infected host, at least in planktonic populations. First, the cell typically has a tough cell envelope evolved to withstand chemical, mechanical and thermal insult. Eubacteria, for example, have a cross-linked peptidoglycan (PG) arranged in a mesh-like layer with interstices that are normally far too small to allow virion release. Second, since the availability of host cells for the progeny is uncertain the timing of lysis may be important. In other words, continuing an infection cycle rather than causing cellular disruption may be a better strategy if the infected cell is in a host-poor environment, so appropriate regulation of the lytic event should confer a significant fitness advantage. In this review, the molecular strategies that have evolved to deal with these issues will be discussed. As the reader should soon discover, the strategies that have already been discovered cover the spectrum of complexity. These stories come mostly from studies focused on the phages of *E. coli* and other model eubacteria and are consequently well documented and genetics-based. However, most of the new information about viral life cycles is derived from “omics” and high-resolution microscopy; moreover, the host is often a poorly characterized pathogenic bacterium or an exotic archaeal species. Far less is established in these systems but even so, enough is already known to guarantee that the lysis mechanisms will be even more diverse and unusual.

In terms of organization, this review will focus first on “Multigene Lysis” (MGL) (Fig. 1), the general strategy used by the *Caudovirales*, complex double-stranded DNA (dsDNA) phages that dominate the prokaryotic virosphere and have genomes containing up to ~700 genes. Phages that use MGL encode at least one lysis protein to target each structural layer of the cell envelope. The minimal set is two proteins: A holin and an endolysin, targeting the cytoplasmic membrane and cell wall (PG) layer, respectively. However, in many cases, other proteins are encoded for regulation of lysis at the functional level or to target additional envelope components, like the outer membrane (OM) of Gram-negative hosts or the mycolate outer layer of some Actinobacteria. The primary platform for unraveling the molecular nature of these lysis systems has been phage lambda, because of

Fig. 1 (A)–(D) The lysis model for lambda-like MGL systems. During phage replication the holin, endolysin and spanins accumulate in the indicated cellular compartments. Holin triggering (B) results in the sudden formation of micron-scale holes in the inner membrane which releases the endolysin into the periplasm where it degrades its substrate peptidoglycan. Spanins are activated by degradation of the surrounding peptidoglycan and cause outer membrane disruption by fusing the inner and outer membrane (C)–(D) at the last step of lysis. (E)–(H): The lysis model for pinholin-SAR endolysin MGL systems. The SAR-endolysin accumulates in an inactive form in the inner membrane. Pinholin triggering (F) results in the formation of ~2 nm “pinholes” that collapse the PMF. Upon depolarization, the SAR endolysin is released from the bilayer and activated to degrade the peptidoglycan (G). The spanins then fuse the IM and OM at the last step of lysis (H). Reprinted from Cahill, J., Young, R., 2019. Phage lysis: Multiple genes for multiple barriers. *Advances in Virus Research* 103, 33–70.

its unparalleled genetic facility, so considerable space is devoted to recounting the work that originally defined lysis protein function in this system. The next section, standing in stark contrast to the complex pathways and sophisticated coordination evident in the MGL systems, is devoted to Single Gene Lysis (SGL) (Fig. 2), the strategy used by the simplest lytic phages, the ssDNA *Microviridae* (~5 kb; ~10 genes) and the ssRNA *Leviviridae* (~4 kb; 3–4 genes). In these systems, a single polypeptide, usually small (50–100 residues), is produced during infection. In the few cases where the molecular basis has been established, the SGL protein acts as an inhibitor of cell wall biosynthesis, causing the term “protein antibiotic” to be invoked. For one class of phages of eubacteria, the filamentous *Inoviridae*, phage release is achieved without lysis, by virtue of extrusion of the viral particle through the intact cell envelope. Finally, a brief overview of how virions are released in archaeal infections will be presented. We hope the archaeal community will forgive our inclusion of these viruses in a phage review; indeed, since many viruses of archaea are morphologically indistinguishable from phages of eubacteria, we will use the term phage for any virus of a prokaryotic cell, rather than switching back and forth from phage to virus in terms of both shared and different lysis features.

Fig. 2 Some Sgl proteins act as “protein antibiotics” by inhibiting different steps of the PG synthesis pathway. The lysis proteins E, Lys^M, and A₂ of phages ϕ X174, M, and Q β inhibit MurA, MurJ, and MurA, respectively.

The Definition of Phage Lysis

It is important to define what is meant here by “phage lysis”. Generally, absent the lysogenic response or some sort of cell defense event, the vegetative phase of a phage infection (i.e., the intracellular production of progeny virions) is invariably lethal to the host. There are reports of alternative outcomes in which virions are produced but the cell remains viable in some sort of carrier state, but these have not been sufficiently well-characterized genetically or physiologically and may reflect heterogeneous outcomes within the infected cell population. The lethality, in terms of loss of genetic viability of the infected bacterial cell, is detectable as soon as irreversible adsorption has occurred, but physiological viability, in terms of macromolecular synthesis and energy metabolism, is maintained until the phage lysis proteins overtly terminate the infection by destruction of the cell envelope. It seems likely that lysis genes were the last essential genes evolved by phages. The primordial phage presumably had no lysis genes and relied on the generalized failure of the cell envelope that would eventually occur as a result of re-direction of the resources of the cell into production of virus particles and the consequent neglect of homeostatic processes needed for envelope maintenance. Thus even in the absence of functional lysis genes, eventually infected cells will simply fall apart, freeing the progeny virions. Among devotees of lysis functions, this type of outcome is called cellular “rotting”, associated with the gradual loss of optical density in an infected culture over a time scale of hours. In contrast, overt lysis imposed by the phage lytic program occurs on a time scale of minutes. Indeed, there is evidence that adjusting the timing of lysis by just a few minutes is a valuable fitness adjustment (see below), sufficient to cause the evolution of regulatory proteins called antiholins. In any case, unlike any other “essential” gene, the holin-negative phenotype includes a dramatic increase in virion accumulation in the infected cell; this can complicate phenotypic analysis but also be of value when assigning holin function.

The Cell Envelope

A brief overview of the cell envelope and the sorting of envelope proteins, is in order, focusing on Gram-negative cell where most of our knowledge of lysis mechanisms lies. The minimum envelope consists of the cytoplasmic or inner membrane (IM), the cell wall or peptidoglycan layer (PG), and the outer membrane (OM); the compartment between the IM and OM is the periplasm (Fig. 3). The IM is a classic phospholipid bilayer but the OM is asymmetric, with an inner phospholipid leaflet and an outer leaflet composed of lipid A decorated with polysaccharide chains featuring phosphate and other anionic moieties. The OM is rich in non-specific porins, pore-forming beta-barrel proteins that allow free diffusion of soluble molecules $< \sim 600$ Da, so in general the pH,

Fig. 3 (A) The outer membrane (OM), peptidoglycan (PG), and inner membrane (IM) are labeled to the left. Lpp and lipopolysaccharide (LPS) are denoted with arrows. (B) Pathways for Sec-mediated secretion (left of the dashed line) or lipoprotein processing (right of dashed line). The precursor forms of periplasmic proteins pass through the Sec translocon and are cleaved by Signal peptidase I (SPI; site denoted by red dash) and released into the periplasm. The lipoprotein cleavage site is denoted with a blue dash (for the gene product) and an arrow (position of the coded cleavage site in the gene). After passing through the Sec translocon, prolipoprotein diacylglyceryl transferase (Lgt) transfers a diacylglyceride group to the sulfhydryl of the Cys marked for lipoylation. Signal peptidase II (SPII) cleaves the N-terminal TMD at the -1 position. Apolipoprotein N-acetyltransferase (Lnt) transfers an acyl group to the free amino terminus of the Cys. The presence of Asp at the $+2$ or $+3$ position determines will result in Lol avoidance for an IM lipoprotein. Conversely, small polar residues at this position will result in the transport of the lipoprotein to the inner leaflet of the OM by the Lol system.

ionic, and small nutrient content of the periplasm reflects the contents of the external medium. Nevertheless, the periplasm is maintained in an iso-osmotic state to the cytoplasm by the regulated production of polymeric membrane-derived oligosaccharides of a size ($MW > 600$) that cannot escape through the porins. The peptidoglycan is a single covalent meshwork made up of glycosidic chains averaging ~ 30 disaccharide units cross-linked by oligopeptide chains and oriented, in *E. coli*, in a generally orthogonal orientation to the long axis of the cell.

In the healthy cell, a proton-motive force (PMF) of ~ 200 mV is maintained across the IM (positive outside), due to the pH difference between the periplasm (external medium) and the cytoplasm ($pH \sim 7.5$) and electrochemical potential. There is no ATP or other energy currency molecule in the periplasm, so energy-requiring steps in the OM require transduction of free energy from the IM to the OM. Where relevant to lysis, the differences in the envelopes of Gram-positive bacteria and in archaeal cells will be discussed below.

Multigene Lysis (MGL) Systems

The Lambda Prophage as a Lysis Platform

The premier MGL system has been that of coliphage lambda, for two main reasons. First, lambda lysis phenotypes are “clean”, mostly because the infection cycle largely spares the host from undue physiological stress. For example, lambda does not interfere with host gene expression or chromosome integrity, whereas other genetic paradigm phages like T4 degrade host DNA and block both host transcription and translation. Thus, rapid onset of the “rotting” state described above does not occur in the lambda system when lysis genes are inactivated. The second main reason is experimental convenience, largely because of a famous repressor allele, cl_{857} . A culture of lysogenic cells carrying a λcl_{857} prophage can be grown at 30°C and induced by a brief heat shock at 42°C . Every cell thus enters the lytic cycle synchronously, and, if variables such as culture to flask volume ratio, shaker speed, media and growth phase are controlled, reproducible “lysis curves”, the plot of culture turbidity versus time, can be recorded. For example, a 25 ml LB culture of the standard *E. coli* K-12 strain MG1655(λcl_{857}) induced at $A_{550} = 0.2$ ($\sim 10^8$ cells/ml) in a 250 mL flask at 250 RPM rotations per min undergoes lysis at 50 min after induction, releasing ~ 100 plaque-forming units (virions) per induced cell. Using these rigorously defined conditions, an experimenter can discriminate between holin alleles that differ in lysis timing by as little as 2 min. Because of the facile nature of this system, it has generally been the practice to characterize the lysis

genes of any particular lytic phage by engineering them into lambda, using recombineering or other recombination-based methods on the prophage, or by using an inducible plasmid clone to complement the lytic defect associated with a lambda lysis mutant. Indeed, this is how most of our knowledge of the T4 lysis system was obtained.

The Lambda Lysis Cassette

The lambda lysis genes are clustered together into a cassette of four genes: *SRRzRz1* (Fig. 4(A)). These are the first four genes of the polycistronic late transcript produced after activation of the single late promoter at 8–10 min after induction. The genes are conveniently arranged in order of action in lysis. *S* encodes the lambda holin, S105, which is an integral inner membrane protein with 3 transmembrane domains (TMDs) in an N-out, C-in orientation. The *R* gene encodes the lambda endolysin, a 15 kDa soluble lytic transglycosylase that cleaves the glycosidic bonds in the PG. The *Rz-Rz1* architecture is striking, with the latter occupying 60 codons in the +1 reading frame of the former. Despite sharing the same DNA, the two cistrons encode entirely different proteins with different envelope destinations. *Rz* is a 153 aa integral IM protein with type II (N-in, C-out) topology, whereas after secretion and processing, *Rz1* is a 40 aa lipoprotein attached to the inner leaflet of the OM (Fig. 4(A)).

Operational Outline of Lambda MGL

Extensive molecular, genetic, biochemical and fluorescence microscopy studies have resulted in the following operational narrative concerning the roles of the lambda lysis proteins. Throughout the morphogenesis period, both the *S* and *R* gene products accumulate harmlessly. GFP-fusion and cross-linking experiments indicate that S105 accumulates as freely-mobile homodimers dispersed uniformly in the IM, while the *R* endolysins are synthesized as soluble, fully active monomers in the cytoplasm (Fig. 4(B)). The *Rz* and *Rz1* proteins accumulate in bizarre heterotetrameric (Rz_2-Rz1_2) complexes formed by heterotypic C-terminal interactions (Fig. 4(A) and (B)). The complex is called the “spanin” since it spans the entire periplasm; the *Rz* and *Rz1* proteins are thus the i-spanin and o-spanin (IM and OM) subunits, respectively. Necessarily, these complexes are engaged in the surrounding PG meshwork from the moment of assembly. For almost all of the latent period, there is no detectable effect of any of the lysis proteins, expressed singly or together, on cell growth and, more relevantly, intracellular virion morphogenesis. This changes dramatically when the holins trigger, which occurs when $\sim 5 \times 10^3$ molecules of S105 have accumulated, which, in the induced wt lysogen, is at ~ 50 min; the accumulation of the other lysis proteins is comparable. Operationally, triggering means that the holin population is suddenly redistributed from a uniform, mobile state into micron-scale lesions, a.k.a. the “S-holes”, detectable in cryo-electron tomographs as enormous interruptions in the lipid bilayer (Fig. 5). These large, non-specific holes allow the endolysin molecules to escape to the periplasm and degrade the PG; this is step two. This in turn liberates the spanin complexes from the encaging PG meshwork, leading to catastrophic outer membrane disruption, the third step in lysis (Fig. 4(B)). The entire time from triggering to overt lysis requires only a few seconds.

Looking Under the Hood of Lambda Lysis

Lambda lysis is the prototype MGL, so a mechanistic understanding would be crucial for phage biology in general. The most interesting questions, and the current views, are:

- (1) What is the structure of the micron-scale “S-hole”?

As noted above, the S-holes are seen as interruptions in the IM in cryoEM tomographs. Typically, there are 1–3 large holes per induced cell, with an average diameter of > 300 nm. Holes of the same character have been observed for two other holins from paradigm coliphages: *gpt* of T4 and *Y* of P2. Nothing is known about the detailed structure of the holes. Chemical accessibility studies have shown that, after triggering, essentially all S105 molecules have one face of TMDs 1 and 3 exposed to the aqueous phase, presumably the lumen of the hole (Fig. 6). Moreover, the total number of S105 molecules roughly corresponds to the number needed to line the holes, assuming two TMDs (~ 1 nm) per holin in the wall, so the available data are consistent with the S-hole having a single-molecule wall of holins, with TMD1 and TMD3 facing the lumen. However, dynamic and “swiss-cheese”-like structures that intermittently expose the TMDs to the aqueous interface of the lumen are also possible. *In vivo*, the holes are big enough to allow the passage of ~ 0.5 MDa homotetrameric R- β gal chimeras (i.e., the entire *R* protein fused to the ~ 1000 aa ω domain of β -galactosidase). Purified S105 has been shown to permeabilize liposomes; moreover, mutant lysis phenotypes, including temperature-sensitive function, are faithfully reproduced in these assays. Despite exhaustive mutant hunts, no host factor has been implicated in S105 function. Moreover, S105 retains lethal function in yeast and mammalian cells, supporting the notion that S105 acts alone *in vivo*. Nevertheless, high-resolution fluorescence microscopy aimed at directly visualizing the holes has not yet been reported for S105 or any holin.

- (2) What is the mechanism of triggering and hole-formation and how is it regulated temporally?

This is the most important question because it is fundamental to the evolutionary role of lysis. Other than the lysis-lysogeny decision for temperate phages, the decision of when to terminate the infection cycle and lyse the host is the only decision made in the infection cycle. The key observable is that for lambda, and for all other defined MGL systems, artificial depolarization of the cytoplasmic membrane causes premature lysis. This applies to addition of energy poisons like cyanide or dinitrophenol or even to the sudden (and usually unintentional) anaerobiosis imposed by briefly interrupting the aeration

of an induced culture (i.e., turning off the shaker for a minute). A reduction of as little as 30% of the PMF is sufficient to trigger lambda S105, so the holin system can be regarded as an exquisitely tuned sensor of membrane integrity and energy metabolism. Another fundamental property of the lambda holin is that highly conservative single-missense changes throughout the length of S105 can advance, retard or abrogate triggering; similar genetic fragility has been observed for other holins. These and other observations have led to a model for timing in which, at a critical concentration, the holin population nucleates the formation of two-dimensional aggregates, designated as “death rafts” (Fig. 6). These rafts are thought to be lipid-depleted due to intimate intra- and inter-molecular TMD-TMD helix interactions. It is proposed that the lipid-depleted rafts have much higher conductance to protons, thus causing instantaneous reduction or collapse of the PMF. The loss of the ~ 0.2 V potential, which translates to a $\sim 10^5$ v/cm electric field across the ~ 3 nm IM, forces a conformational change in the holin leading immediately to formation of the holes. Note that all of this occurs in 10–20 s after a latent period of ~ 50 min throughout which the PMF is maintained at normal levels, as determined by experiments using flagella rotation as a non-invasive readout.

In this model, the extreme mutational fragility of S, and other holins is due to effects of the missense changes on the multiple helix-helix interactions involved in the pathway from mobile homodimer to raft. The notion of a critical concentration for aggregation is derived from studies of the formation of the purple membrane in halobacteria. After induction, the bacteriorhodopsin monomer initially accumulates as a freely mobile monomer before, at a critical concentration, suddenly nucleating the two-dimensional light harvesting array. Similarly, conservative changes at intermolecular contact points in the some of the seven TMDs elicit unpredictable changes in the timing of purple membrane nucleation.

(3) Why is the spanin necessary and how does it disrupt the OM?

Although the holin-endolysin pathway has been recognized for decades, the requirement for OM disruption was only recently discovered. The key result was that inductions of a lambda lysogen carrying nonsense mutations in both the *Rz* and *Rz1* genes terminated not in lysis but instead in a spherical cell morphology. Cryo-EM images show that the PG layer was missing, so the loss of rod shape reflected the capacity of the OM to withstand the osmotic pressure of the cell. Structural predictions indicate that *Rz* has two coiled-coil alpha helices in its periplasmic domain, whereas *Rz1* largely unstructured due to its high proline content (Fig. 4(A)). Biochemical experiments support these predictions. Both *Rz* and *Rz1* form homodimers that are covalently linked by homotypic intermolecular disulfide bonds, based on Cys residues at *Rz* positions 99 and 152 and *Rz1* position 29 (Fig. 4(A)). Although the Cys at position 99 is dispensable, the lytic function of the complex requires at least one disulfide bond in either of the other two positions.

Based on the similarities of spanins to membrane fusion systems (coiled-coil structure and membrane-spanning complex) it was hypothesized that spanins disrupt the OM by causing the IM and OM to fuse during lysis (Figs. 1(C–D) and 4(B)). Genetic analyses lent support to this notion, implicating two coiled-coil helix domains in *Rz* and the proline-rich region in *Rz1* as key elements in the lytic function. Proline-rich stretches have been shown to be essential for the reovirus FAST fusion proteins and coiled-coil domains are a conserved feature across many fusion systems. Forward mutation and suppressor analysis suggested that most mutants blocked the ordered conversion from the extended form of the complex to the hairpin conformation.

A Second Strategy: Pinholins and SAR Endolysins

A second general type of MGL is represented by the lysis system of the lambdoid coliphage $\phi 21$. Although the $\phi 21$ lysis cassette is arranged syntentically to lambda, which resulted in its genes being assigned homologous names, there are fundamental differences in these two MGL systems. First, the *S*²¹ gene encodes a 68 residue “pinholin” (*S*²¹68), with two TMDs in N-in, C-in topology. Biochemical and microscopic studies indicate that this pathway is operationally similar to the lambda pathway, in that the pinholins accumulate as freely-mobile homodimers in the IM. However, after triggering, the pinholins form many more ($\sim 10^3$) and much smaller holes (~ 2 nm) “pinholes”. Moreover, pinholin function requires unprecedented topological dynamics, in that TMD1 must exit the bilayer before triggering (Fig. 4(C)). Indeed, TMD1 is dispensable and thus can be considered an intramolecular negative-regulatory domain.

Clearly, the pinholes are too small to allow the release of folded endolysins, so the *R*²¹ endolysin has a special secretory properties conferred by its N-terminal SAR domain. This signal engages the host *sec* translocon like a typical N-terminal TMD, so that *R*²¹ accumulates in the periplasm tethered to the IM (Fig. 4(C), left). Importantly, this form is enzymatically inactive, thus avoiding premature lysis. Equally important is that the SAR domain is metastable in the bilayer, so that it escapes the membrane

Fig. 4 (A) Left: Cartoon of lambda spanins *Rz* and *Rz1* shown within the cell envelope. The homotypic intermolecular disulfide linkages are shown. Right: The lambda lysis cassette is shown. Expression of these genes is under control of the late promoter *pR'*. The *Rz1* gene is embedded in the +1 reading frame of *Rz* and the following functional domains for spanin gene products have been identified by genetic analysis: NTMD = N-terminal transmembrane domain, JM = juxtamembrane region, CC1 = alpha helix with predicted coiled-coil domains, CC2 = distal coiled-coil domain, PRR = proline-rich region. (B) Model for MGL systems encoding a soluble endolysin: The holin forms holes in the inner membrane that allow the endolysin to access the peptidoglycan. After the endolysin degrades the peptidoglycan, the spanins activate and undergo a conformational change that causes fusion of the IM and OM. (C) Model for MGL systems encoding a pinholin-SAR endolysin: During triggering the pinholin TMD1 exits the bilayer and TMD2 oligomerizes into ~ 2 nm pinholes in the IM. The formation of ~ 1000 pinholes causes depolarization of the membrane, resulting in the release and activation of the SAR endolysin from the bilayer. Reprinted from Cahill, J., Young, R., 2019. Phage lysis: Multiple genes for multiple barriers. *Advances in Virus Research* 103, 33–70.

The arrow indicates the lesion in the inner membrane. (B) 3D reconstruction: The outer membrane is shown in blue and the inner membrane is shown in orange. Scale bar is 250 nm. Reprinted from Dewey, J.S., Savva, C.G., White, R.L., *et al.*, 2010. Micron-scale holes terminate the phage infection cycle. *Proceedings of the National Academy of Sciences* 107, 2219–2223.

Fig. 6 Model of lambda holin function. Top-down view of the S105 holin, depicting a hydrophobic face (black) and a hydrophilic face (white) for TMDs 1 and 3. The holin accumulates as a dimer with the hydrophilic faces sequestered intramolecularly. As the holin accumulates in the inner membrane there is an increase in the oligomeric state (dimers to oligomers). At a critical concentration the holin molecules nucleate into rafts with the hydrophilic faces oriented toward each other. The rafts are thought to be large enough to disrupt the PMF of the cell. When the cell depolarizes the holin transitions to hole-forming structure, with lipid outside (gray) and the hydrophilic faces of TMDs 1 and 3 facing an aqueous lumen (white). Although rafts have been visualized using holin-GFP chimeras, the arrangement of holin molecules in rafts is inferred (asterisks) from the final hole-forming arrangement. The cartoons of the rafts and the hole are not drawn to scale. Nothing is known about the two-dimensional organization of the rafts, so the linear arrangement is shown purely to indicate and intramolecular sequestration of the hydrophilic surfaces of TMDs 1 and 3. Reprinted from Cahill, J., Young, R., 2019. Phage lysis: Multiple genes for multiple barriers. *Advances in Virus Research* 103, 33–70.

when the pinholin triggers and, as a result of the massive formation of pinholes, the PMF is completely collapsed. Release from the bilayer causes refolding of the SAR endolysin to an active form, and the PG is subsequently degraded (**Figs. 2** and **4(C)**).

A Second Type of Spanin

Coliphage T1 has a special place in the history of phage biology, being the first member of the “Seven Dwarves” (phages T1–T7) designated by the Delbrück phage group in the 1940s as the sole permissible experimental systems. I-spanin and o-spanin genes were easily identified in T2 through T7 by virtue of the distinct secretory signals (an N-terminal TMD for the former and an OM SPII signal sequence for the latter) and the fact that the genes were always closely linked (either embedded as in lambda, overlapped as in P2, or adjacent as in T4). In the T1 lysis cassette, the cistron in the position normally occupied by the i-spanin/o-spanin genes encoded a protein, gp11, with unprecedented dual targeting signals: an N-terminal OM lipoprotein signal and a C-terminal TMD that would span the IM (**Fig. 7**). Genetics and biochemical approaches confirmed the dual targeting, indicating that gp11, once synthesized and processed by the LOL OM lipoprotein export pathway (**Fig. 3(B)**), connects the OM and IM as a single polypeptide. Since gp11 fully complemented the lysis defect of an induced lambda *Rz_{am}Rz1_{am}* lysogen, it has been

Fig. 7 Cartoon of the T7 u-spanin gp11, attached to the OM with an N-terminal lipid anchor and embedded in the IM by a helical C-terminal TMD.

designated as a unimolecular spanin (*u*-spanin), in contrast to the *i*-spanin and *o*-spanin subunits of the two-component spanin. Unlike the *i*-spanin, which is rich in coiled-coil helical structure, the *u*-spanin periplasmic domain is dominated by stretches of predicted beta-strand conformation. The length of the periplasmic domain, if fully extended, closely matches the observed width of the periplasm.

Nothing is known about the molecular mechanism by which the *u*-spanin disrupts the OM. However, both the two-component spanin and the *u*-spanin appear to be negatively regulated by the intact PG. This is based on experiments in which the spanin complex was capable of causing lysis in an endolysin-independent fashion if the PG layer was sufficiently compromised by starvation for the precursors of the cross-linking polypeptides. This common feature suggests that the *u*-spanins also disrupt the OM by fusing it with the IM; in this regard, gp11 resembles class-II viral fusion proteins, primarily due to the dominance of β -structure in its periplasmic domain. Presumably, the step of bringing the IM and OM together is facilitated by collapse of the periplasmic domain from its original extended form into beta-sheet structures. The C-terminal TMD plays no role specific other than anchoring in the IM, because an artificial TMD can replace the original TMD without affecting lytic function.

Regulation of MGL

Dual start holin genes: Holin-antiholin pairs

For both canonical (large-hole) holins and pinholin systems, holin accumulation controls the timing of lysis. However, in all the phage systems that have received sufficient study to allow a thorough analysis of gene expression, the MGL genes are co-transcribed with all the morphogenesis genes, ruling out transcriptional regulation. The best studied example of lysis regulation is in lambda, where the *S* gene encodes a second protein, S107, by virtue of an upstream translational start. Although S107 and S105 differ only by the two extra N-terminal residues in the former, S107 acts as a negative regulator, or “antiholin” of S105 (**Fig. 8(A)**). The root of this antagonistic behavior is that the extra positive-charged Lys2 residue of S107 prevents TMD1 from entering the bilayer, rendering S107 into a non-functional topology with only TMD2 and TMD3 in the bilayer. S107 preferentially heterodimerizes with S105, and, since the normal ratio of S105:S107 is ~ 2 , only 1/3 of the freely diffusing dimers are S105:S105 homodimers constituting the mass action pool that leads to triggering. The ratio of S105 to S107 is controlled by an RNA stem-loop structure that overlaps the ribosome binding sites for Met1 and Met3. The potential effect of S107 regulation is mainly negative; eliminating the S107 gene start has only a minor effect on lysis timing, advancing lysis by ~ 5 min, but increasing S107 to or beyond the level of S105 blocks spontaneous lysis entirely. There is some evidence for host factor control of the stem-loop formation and thus of the S105–S107 ratio, but the molecular signal, if any, that might increase the proportion of antiholin starts has not been identified. In any case, when the S105 population reaches its critical concentration and the PMF is collapsed, the S107 molecules are converted to the N-out, C-in topology. At least in principle, this instantly triples the pool of functional holin molecules available for hole formation, contributing to the saltatory, or “all or nothing”, character of lysis regulation. However, how much these the converted S105–S107 heterodimers actually contribute to hole structure has not been determined.

Fig. 8 Comparison of the dual start holin/pinholin motifs and a model for the inhibitory role of the antiholin for lambda (left) and phage 21 (right). The start codons are underlined for *S105*, *S107*, *S²¹71* and *S²¹68* and the first residues of the translational sequence for the holin/pinholin (*S105* and *S²¹68*) or antiholin/antipinholin (*S107* and *S²¹71*) are shown aligned to their respective codon. For both antiholins, the positive charge on the N-terminal extension blocks a topological change for TMD1. Therefore, *S107* is unable to enter the bilayer and *S²¹71* is unable to exit the bilayer. In this topology *S107* and *S²¹71* are inhibitory to their cognate holin. Upon triggering, the topological blockage is removed and the antiholins functionally become holins, joining the triggering pathway toward hole formation. Reprinted from Cahill, J., Young, R., 2019. Phage lysis: Multiple genes for multiple barriers. *Advances in Virus Research* 103, 33–70.

The prototype pinholin gene, *S²¹*, has a similar “dual start” motif, with opposite topological consequences. The antiholin product, *S²¹71*, is produced from translational initiation three codons upstream of the pinholin start and has an extra positive-charge residue that prevents TMD1 from exiting the bilayer. As noted above, TMD1 of the pinholin is a built-in inhibitory domain that must exit the bilayer before TMD2 can proceed to hole formation (Fig. 8(B)). The presence of the extra basic residue at the cytoplasmic end of TMD1 blocks its release into the periplasm and thus inactivates the heterodimer in terms of pinhole formation. Again, the PMF collapse deriving from triggering by the uninhibited pinholins should, in principle, allow TMD1 of *S²¹71* to escape from the membrane and thus activate the inhibited heterodimers. Based on the rigorous characterization of the lambda and ϕ 21 systems, other dual-start holins have been noted and some of them confirmed, usually by cloning into inducible expression vectors in *E. coli*. However, neither of the well-characterized dual start systems can be considered real-time regulation, since the ratio of the holin and pinholin appears to be set and no physiological condition for altering it is known.

Real-Time Regulation of Holin Function: Phage T4 Lysis Inhibition

The T4 holin, endolysin, i-spanin and o-spanin are encoded by genes *t*, *e*, *pseT.3*, and *pseT.2*, respectively. When not under LIN regulation (discussed below), the lysis pathway is analogous to lambda. The T holin forms holes at the time of triggering, which releases soluble endolysin E into the periplasm where it degrades the PG. Like lambda, the last step of lysis is the disruption of the OM by the two-component spanin complex assembled from the i-spanin PseT.3 and o-spanin PseT.2. However, the topology and primary structure of the T4 holin is grossly dissimilar to that of lambda. Unlike other holins, *gpt* has a single TMD, a large C-terminal periplasmic domain (163 aa) and a substantial (32 aa) N-terminal cytoplasmic domain (Figs. 9 and 10). Nevertheless, despite the disparity in holin primary structure, cryoEM studies indicate that there is little difference in the size and number of T-holes compared to lambda S-holes. The T4 system has an additional level of regulation, reflected in the phenomenon of “lysis inhibition” (LIN), first documented in the 1940s by the Delbrück group. If a T4-infected cell is super-infected at 5 min or more after the initial infection, lysis is blocked, at least temporarily. Continued superinfection can extend the LIN state for hours, leading to hyper-accumulation of progeny virions intracellularly, before spontaneously collapsing. The LIN state can be prematurely collapsed by addition of uncouplers or energy poisons, indicating that, as expected, LIN reflects inhibition at the level of holin triggering. Accordingly, there are many missense mutants of *gpt* that do not support LIN and instead trigger lysis at ~25 min after infection, irrespective of super-infection. The requirement for at least 5 min post-infection before superinfection stems from the need to synthesize four early T4 proteins: RI, RIII, RIV (also Spackle or Sp), and Imm. It is thought that RIV and Imm both function to block the tail tube of the super-infecting T4 from penetrating the IM and ejecting the capsid contents into the cytoplasm. RIV inhibits the tail lysozyme responsible for penetrating the PG layer; Imm is a membrane protein that may interfere with the temporary permeabilization of the IM. As a result, the contents of the capsid head are ejected ectopically into the periplasm. The contents include the 170 kb gDNA and > 1000 protein molecules. It is thought that something in this mélange is the signal for LIN (Fig. 9), since superinfection with T4 “ghosts”, in which the T4 capsid contents have been released osmotically, does not cause LIN.

Recent work addressing the molecular basis for LIN have demonstrated that RI and RIII are antiholins and effect LIN by binding to the *gpt* holin and inhibiting the triggering pathway. The key LIN component is RI, which has a SAR domain and a 75 aa C-terminal

Fig. 9 Model for T4 lysis and lysis inhibition. Left: During a single infection, RI is degraded by DegP. The T holin triggers at the normal ~25 min time (after infection), which results in the release of endolysin into the periplasm to degrade the peptidoglycan. The subsequent spanin-mediated outer membrane disruption step follows (not shown). Right: Superinfection at >5 min after infection results in ectopic localization of the capsid contents into the periplasm, in the inhibition of DegP-mediated degradation of RI. Stabilized RI dimerizes and binds T dimers, blocking it from further oligomerization. In this state, a symmetric binding site is provided for dimeric RIII binding. Formation of this heterohexameric complex stably maintains the LIN state.

Fig. 10 The founding members of each class of holins are shown along with their membrane topology.

periplasmic domain (CTD). After synthesis, RI transits to the periplasm where it is rapidly degraded if expressed alone or during single infections, whereas superinfection from a second T4 particle stabilizes RI. The rapid inactivation of RI is caused by the presence of its SAR domain. Replacement of the RI SAR domain with a normal secretory signal sequence resulted in the secretion of a proteolytically stable truncated form of RI (sRI) to the periplasm; this species can impose LIN on *gpt* irrespective of superinfection. LIN requires the formation of equimolar complexes between the periplasmic domains of RI and *gpt*; these complexes block progression of *gpt* into the triggering pathway. The RIII protein is a 95 aa soluble cytoplasmic species that binds to the N-terminal cytoplasmic domain of *gpt*. RIII alone has only a minor effect on *gpt*-mediated lysis but expression of RI and RIII together can establish a stable LIN state without the need for superinfection. The simplest model incorporating these observations is that RI and RIII act as periplasmic and cytoplasmic antiholins, respectively, with RIII acting to stabilize the RI-*gpt* complex (Fig. 9).

T4 lysis and the LIN response constitute the oldest genetically-defined phenomena in phage biology and arguably in modern molecular genetics. With the progress achieved in identifying the molecular components and their interaction domains, the remaining mystery occluding a clear picture of this elegant regulatory scheme is the nature of the LIN signal generated by the super-infecting phage. In addition, the *gpt* holin is itself an enigma. It is unclear how a large globular periplasmic domain, roughly

5–6 nm in diameter, can be arranged in two-dimensions to allow the single TMD (~1 nm diameter) to oligomerize and make the micron-scale holes observed by cryo-EM. One possibility is that the N-terminal domain, which at 32 residues is much larger than the cytoplasmic domains of other holins, may rearrange to form a second TMD that could be assembled into the wall of the hole.

MGL Diversity

There are thus two distinct molecular strategies for each step in phage-mediated lysis of Gram-negative hosts: holins and pinholins targeting the IM, soluble endolysins and SAR endolysins targeting the PG, and the two types of spanins, two-component (i-spanin/o-spanin) and unimolecular (u-spanin). With the exception that pinholins require SAR endolysins, there are six possible combinations, all of which have either been encountered in nature or constructed in the laboratory and found to be functional, at least in terms of achieving lysis with kinetics that would be useful for a phage. The term “canonical” has been applied to the large-hole forming holins and soluble endolysins to distinguish them from pinholins and SAR endolysins. Each functional class of lysis proteins has its own profile in diversity.

Holin Diversity

The term holin was coined to denote proteins that form lethal and non-specific holes in the IM. As established in coliphage systems, the holin has two roles, serving to release the endolysin into the periplasm as well as to function as the “lysis clock”. The clock function refers to the fact that holins control the initiation of lysis and thereby govern the length of the vegetative phase. Holin homologs have been found in all three domains of life and there are more than 60,000 unique entries for holins in the NIH identical protein database. In recent years, there have been efforts to categorize this very diverse group of proteins as well as understand the functional role of holin homologs outside of phage lysis.

Holins are classified based on the number of TMDs: Class I, II, and III holins have three, two, and one TMD(s), respectively (Fig. 10), and there is bioinformatic evidence for holins with four TMDs. The immense diversity makes them difficult to identify through homology. Holin gene calling is limited to searching for a small integral IM protein with up to four TMDs located near an endolysin. In 2013, Reddy and Saier identified 52 families (there are now 67) of established or putative holins, which can be viewed on the TCDB (transporter classification database). Using statistical analyses, 21 of the 52 families were found to be made up of seven superfamilies; i.e., the members are homologous but distantly related.

The number of different holin families with distinct topologies suggests that the diversity is a product of convergent evolution. The most striking demonstration of how holins that are found in one domain could also function in another was done with Bax and Bak, which are involved in the apoptotic response in mitochondria. Bax/Bak are encoded in the nucleus and cause permeabilization of the mitochondrial OM. Interestingly, these proteins were shown to function as holins in *E. coli*. The authors showed that active Bax or Bak formed large enough holes to release lambda endolysin into the periplasm, causing lysis. It should be noted however, that these proteins do not replicate the clock function of “real” holins, and the size of the lesions produced is unknown.

Some phages of Gram-positive and Mycobacterial hosts require two separate genes for holin function, the first report of which was for the defective prophage PBSX of *Bacillus subtilis*. In this system, both *xhlB* (predicted class II holin) and *xhlA* (class III but with large N-terminal domain) are required for endolysin release. In another example, *Bacillus* phage SPP1 holin activity requires genes 24.1 and 26, encoding proteins with class I and class II topologies, respectively. In an unusual twist on lysis gene regulation, it was reported that gp24.1 is constitutively expressed with the endolysin, thus allowing gp26, which is a late transcription product, to serve as the clock.

The mycobacteriophage Ms6 lysis system has been reported to use two holins, gp4 and gp5 (discussed below). Taken together, there is increasing evidence for co-holin systems. It would be interesting to address why these systems evolved to require two-components; e.g., perhaps one holin component functions to alter the timing of lysis in response to cellular or environmental signals.

Endolysin Diversity

Endolysins have four different mechanisms of targeting linkages essential to the integrity of the cell wall. Amidases and endopeptidases break oligopeptide crosslinks, whereas glycosylases and transglycosylases target glycosidic linkages. The lambda endolysin is transglycosylase that cleaves the β -1,4 glycosidic linkage between MurNAc and GlcNAc, resulting in the formation of a cyclic 1,6-anhydromuramic acid cleavage product. In contrast, the endolysin of T4 and phage 22 are “true lysozymes,” which hydrolyze the bond between MurNAc and GlcNAc using a glycosidase catalytic triad (E-xxxxx-C/D-xxx-T, or a variant). The hydrolysis reaction releases a disaccharide product with reducing ends. The T7 endolysin is a product of gene 3.5 and the best-characterized amidase. Interestingly, gp3.5 has been shown to bind and inhibit T7 RNA polymerase. Despite the variety of mechanisms, the difference in enzymatic activities is not critical to the overall lysis reaction; complementation studies have demonstrated that endolysins will work with any holin. Moreover, the endolysin is usually produced in great excess over what is needed for lysis; thus some amber nonsense alleles of lambda *R* do not block lysis, due to <5% read-through of the UAG stop codon.

Recently, a comprehensive analysis was done on endolysins from 890 phage genomes that were isolated from 64 different bacterial genera. Endolysins were shown to be very diverse, perhaps owing to the large variety of PG chemotypes. The 723 putative endolysins ranged from 72 to 578 residues in length, using 24 different catalytic domains and 18 different cell wall-binding domains organized with 89 different architectures. From this list, there were 103 endolysins identified with a SAR domain. Interestingly, except for four endolysins from phages of lactococcal hosts, endolysins with predicted SAR domains were exclusively from phages infecting Gram-negative bacteria (especially *Enterobacteriaceae*). Moreover, there are significant differences in canonical endolysins from Gram-negative versus Gram-positive bacteria. In general, endolysins from phages of Gram-negative hosts are smaller with a single domain responsible for both binding and catalysis of the PG. In contrast, phages infecting Gram-positive bacteria produce endolysins with the cell-wall-binding domain separated from the catalytic domain. It has been suggested that the separated domain architecture functions to anchor the endolysin to the PG and prevent collateral damage during lysis. In other words, lysing cells might release endolysin which would destroy the exposed peptidoglycan of neighboring cells, which are potential hosts for the next infection cycle.

Spanin Diversity

Recently, a comprehensive bioinformatic study was done to examine the diversity and conservation of spanins for phages with Gram-negative hosts. Most phages (528 out of 677 genomes) employ two-component spanins, i.e., encoding an i-spanin and an o-spanin. Within this set, 34% were arranged like lambda, with the o-spanin gene totally embedded within the i-spanin. The most common arrangement was overlapped (like phage P2), accounting for 43% of the genomes and the remainder of the genomes had separated architecture (like T4). Spanins were then grouped into families so that members shared >40% identity over >40% of the length of their sequence. Surprisingly, this revealed >100 families and there were 99 and 65 singletons for i-spanin and o-spanins, respectively. The trend continued for the 58 genomes with u-spanins, with 13 families and 6 singletons. The large number of families, especially singletons, shows that spanins are very diverse proteins.

An interesting question that stemmed from the study above is why no spanin genes could be identified in 13% of the genomes. One problem is that annotation of the spanins depends on the identification of the signal peptidase II (SPII) processing site, or lipobox, in either the o-spanin or u-spanin sequence. The algorithm for assignment of SPII sites is problematic for protein sequences of less than 70 residues, and utterly dependent on accurate determination of the translational start. We have found the latter is problematical in many phage genomes in the database, presumably because of the extensive gene crowding and codon overlap. However, some phages, like the T7-like podophages, have genome organizations that are relatively easy to annotate and where the existence of any lipobox-containing sequences can be ruled out. For example, the T7-like phage Petty of *Acinetobacter baumannii* was shown to cause the rapid and explosive lysis characteristic of MGL. The lysis morphology is significant because it indicates that the lysis pathway of Petty does not stall at the OM disruption step. Petty encodes a holin and an endolysin but careful analysis of all possible reading frames revealed that no lipobox-containing reading frame exists. This supports the idea that Petty and presumably other spanin-less phages disrupt the OM by a yet-to-be discovered OM disrupting protein.

MGL in Gram-Positive Hosts

Of all the various lysis proteins, the one class that has attracted the vast majority of enzymological and biotechnological interest in lysis has been focused on the endolysins of phages with Gram-positive hosts. This stems from the fact that the endolysins of these phages can be applied from the outside and cause efficient bacteriolysis, as documented in early work using lysates generated by *Streptococcus* phage C1 and later with purified C1 endolysin. The use of such lysins as anti-bacterials has since become a vibrant field of its own. Nevertheless, how endolysin activity is coordinated with the infection cycle has not been studied extensively in Gram-positive systems. In the relatively few cases where the functional identification of holins in phages of Gram-positive hosts has been accomplished, it was usually done either by complementation of the lysis defect of lambda S mutants (see above), or by cloning the putative holin and endolysin genes in an inducible expression vector in *E. coli*. In principle, MGL in most Gram-positive systems should be simple, with only the holin and an endolysin needed. For example, the *B. subtilis* phage phi29 has a small genome and has been subjected to extensive genetic and molecular analysis, revealing gene 15 to be the endolysin gene. The adjacent gene 14 was predicted to be an integral membrane protein with 3 TMDs and a potential dual start, which would yield a 131 aa antiholin and 129 aa class I holin; these predictions were unambiguously confirmed by inducing clones of this simple lysis cassette in *E. coli*. However, many Gram-positive species are capable of autolytic physiological responses, often as part of sporulation responses, natural transformation pathways and stationary phase adaptation. Accordingly, holin-endolysin gene cassettes have been identified in all pneumococcal phages and some have been shown to be functional in *E. coli*, but there are indications that the lessons may not be so simple. For example, it has been reported that in pneumococcus phage SV1, the endolysin does not require the holin for escape from the cytoplasm and localization to the PG, despite lacking any secretion signal. Instead the holin is required to activate the endolysin by collapsing the membrane potential. In addition, efficient lysis in infections by SV1 requires also the participation of the powerful host autolysin LytA, which is also activated by the depolarization of the membrane. The holin-independence of the endolysin may reflect the use of the cryptic secretion system that enables cytoplasmic enzymes to partition to the cell surface and "moonlight" as adhesins, as has been documented in *Streptococcus* for the glycolytic enzyme GAPDH and other proteins. However, the subcellular distribution of LytA during different growth phases has been quantified,

leading to the conclusion that its partial (~5%) extracellular localization derives from “fratricidal” lysis events in a fraction of the cells during exponential phase, rather than a cryptic secretion pathway. In this model, lysis is prevented at the substrate level, in that the healthy PG biosynthesis machinery blocks access of the endolysin to sensitive sites. Entrance into stationary phase or other stressful conditions lead to incapacitation of the machinery, exposing the PG at critical sites, especially the developing septum. This leads to a lysis cascade, with the system primed by the low level of externalized LytA in exponential phase. This rationale provides a common basis for the apparent activation of LytA, and by extension, to the SV1 endolysin, by antibiotics that interfere with PG biosynthesis and depolarization by holin triggering.

There are other reports of holin-independent localization of endolysin in phages of Gram-positive hosts, including what appears to be a SAR endolysin in the *Lactobacillus* phage phiPYB5. The earliest, pre-dating the discovery of SAR endolysins, was for the *Oenococcus* phage fOg44, where the endolysin was shown to be secreted by a standard SPI signal sequence. Nevertheless, the secreted mature protein did not immediately cause lysis but, instead, became muralytically active when the holin triggered to permeabilize the membrane. It should be noted that the lysis cascade scheme mentioned above might apply here too; i.e., the depolarization may interrupt normal PG synthesis, exposing otherwise masked substrate structures to the secreted fOg44 endolysin. Indeed, this perspective provides a molecular rationale for the proposition, promulgated recently by Fernandes and Sao-Jose, that, in infections of Gram-positive cells, the central role of holins is the depolarization of the cytoplasmic membrane rather than the release of endolysin.

Lysis in Mycobacteria

The members of the order *Corynebacteriales* have a three-layer envelope, like the Gram-negatives, but instead of the asymmetric phospholipid-LPS OM, have an outer surface layer of mycolic acid, the “mycomembrane” (OMM), connected to the PG by arabinogalactan. Thus phages with hosts of this order should require something operationally analogous to the spanins for disruption of the OMM. To this end, most mycophages encode a protein called LysB, after the prototype first studied in phage Ms6. LysB has esterase activity that cleaves the linkages between the mycolic acids and the arabinogalactan. Genetic studies in *M. smegmatis* phages showed that defects in LysB are associated with substantial losses of progeny virions due to entrapment in the host debris, although deletion of the *lysB* gene does not abrogate plaque-formation. Presumably LysB is secreted through the holin lesion, although this has not been explicitly demonstrated. Moreover, studies of LysB localization and coordination with respect to the endolysin have not yet been reported.

One might view the finding that mycophage use a lysis protein to disrupt the OMM as an indication that MGL in the Mycolata closely parallels MGL in Gram-negative hosts. However, the same Ms6 lysis system, which has been subjected to rigorous genetic and molecular analysis, has unique features that dispel any such notion. The first surprises concern the LysA endolysin gene, which has two translational starts 143 codons apart, thus encoding full-length LysA384 and a shorter product, LysA241. Both forms have amidase activity and PG binding motifs and both are required for efficient lysis and release of progeny. The gene immediately upstream of *lysA*, gene 1, encodes a 78 aa acidic polypeptide that forms oligomeric complexes with the endolysin and acts as a chaperone for its *secA*-dependent externalization in Ms6 infections of *M. smegmatis* and in inductions in *E. coli*. There is nothing resembling a signal sequence in LysA, so this is just as mysterious from the perspective of the well-characterized function of the Sec translocon as it is from our general understanding of how lysis proteins are localized. In addition, the shorter *lysA* product lacks the N-terminal domain required for gp1 binding, so there is no model for how it transits the membrane. Moreover, the apparent lysis cassette terminates in two genes encoding small membrane proteins, gp4 and gp5. The former has predicted topology that fits a standard class II (2 TMDs, N-in/C-in) holin, whereas the latter has a single TMD with unambiguous N-out, C-in topology defined by extraordinarily hydrophilic N- and C-terminal domains. Experiments with clones in *E. coli* indicated the two proteins oligomerize and function together in lysis, but single-step growth experiments with Ms6 mutants suggested that gp5 has antiholin character. Taken together, these rather heretical conclusions indicate that MGL systems in the mycolata and other Gram-positive hosts may have many new working parts and regulatory features that deserve attention.

Single Gene Lysis (SGL) Systems

Although the dsDNA phages dominate the virosphere, there are two classes of small lytic phages with single-stranded genomic nucleic acids that are widespread in nature: the single-strand circular DNA *Microviridae* and the ssRNA *Leviviridae*. Despite the vast biological and evolutionary differences, they all achieve lysis without deployment of a muralytic enzyme. Instead each of these phages encodes a single lysis protein that causes the host to undergo autolysis. Here we will refer to each lysis protein as an Sgl, but it must be noted that the SGL proteins are in general unrelated to each other except in sharing the same operational strategy.

ϕ X174 E: The First “Protein Antibiotic” Sgl

The ϕ X174 microvirus is a phage of many “firsts.” It was the first DNA genome to be sequenced and the first genome to be synthesized *in vitro*, and the first to have its Sgl to be characterized. The life cycle is simple; after penetration of the 5 kb circular, single-stranded gDNA into the cytoplasm, all 10 genes are transcribed constitutively from multiple promoters. The Sgl of the prototype microvirus ϕ X174 is protein E, encoded in a reading frame embedded in the +1 register in gene D (Fig. 11), which

Fig. 11 Sgl phage gene maps. All the known architectures of SGL phages are shown, including the ssDNA coliphage ϕ X174 and five *Leviviridae*: Qb and MS2, which are specific for the F conjugation pilus; PhiCb5, specific for the *C. crescentus* TAD polar pilus; M, specific for the IncM conjugation pilus; and AP205, specific for the type IV pilus of *Acinetobacter*. The *sgl* genes are colored blue. The Qb Sgl protein is also the Mat protein, designated A_2 historically. The A_1 protein is a minor capsid protein generated by read-through of the coat stop codon. Capsid proteins are colored black. All L-like *sgl* genes are situated overlapping the *coat-rep* junction, as in MS2, except for AP205. The PA-type *sgl* genes (ϕ X174, Qb, and M) have diverse locations. The lytic mode of phiCb5 is unknown but thought to be PA-type. Originally published in Chamakura, K., and Young, R., 2019. Phage single-gene lysis: Finding the weak spot in the bacterial cell wall. *Journal of Biological Chemistry* 294, 3350–3358.

encodes the scaffolding protein essential for capsid morphogenesis. The *E* product is a 91-residue type-I integral membrane protein in which the N-terminal 34 residues (E_{NTD}) are conserved in other *Microviridae* and essential for lytic function, whereas the highly basic (+11 net charge), proline-rich C-terminal domain (E_{CTD}) can be replaced by heterologous domains like β -galactosidase or GFP without impairing lytic function. *E* exerts its lytic function by acting as a non-competitive inhibitor of *MraY*, a conserved membrane protein which catalyzes the formation of Lipid I, the first lipid-linked intermediate in the pathway for biosynthesis of PG precursors (Fig. 2). *MraY* has 11 TMDs, and resistance to *E* can arise by mutations in TMDs 5 and 9 that reduce binding affinity. Conservative mutations in hydrophobic residues along one face of the TMD in *E* and in residues near its presumed periplasmic interface can affect either *E* binding or the capacity for non-competitive inhibition. These data are most consistent with a model in which one face of the single TMD of *E* interacts directly with TMDs 5 and 9 of *MraY*.

E lysis requires a host factor, *SlyD*, a FKBP-type peptidylprolyl-cis-trans-isomerase cytoplasmic chaperone. In a *slyD* background, *E* is extremely unstable. This likely reflects the requirement of folding of the E_{CTD} , because *E* fusion proteins carrying heterologous CTDs do not require the chaperone. It is possible that the E_{CTD} has evolved as a regulatory domain responsive to the host *SlyD* activity. However, nothing is known about how *SlyD* levels or activity vary with host physiology.

E lysis, either in ϕ X174 infections or from inductions of a plasmid clone of *E*, occurs only in growing cells that are undergoing cell division; consistent with the biochemical studies, *E*-lysis begins about 20 min after the cessation of PG biosynthesis. The morphology of *E*-mediated lysis is striking, in that nearly all the lysing cells undergo mid-cell blebbing. The production of these septal catastrophes is indistinguishable from the cell fate imposed by cell wall antibiotics. *E* was thus the founding member of a general class of Sgls designated as the “protein antibiotics” (PA). ϕ X174 is the prototype of the *Bullavirinae* subfamily of the *Microviridae*, the only group of this ubiquitous phage type that has been the subject of significant experimentation. *E* is conserved, especially in the N-terminal domain essential for lysis, in all the 15 other *Bullavirinae*, each of which is an enteric phage demonstrated to have lytic function and plaque-forming ability. To assess the diversity and distribution of *E*-like lysis proteins in the other *Microviridae*, we have restricted analysis to the curated RefSeq database. There are 45 other *Microviridae* genomes in RefSeq, divided into the *Gokushovirinae* subfamily (15 phages) and a group of 30 unclassified phages, including members from hosts as diverse as *Chlamydia* and *Bdellovibrio*. No protein related to *E* is encoded by an annotated gene in any of these genomes or in any genome outside the *Bullavirinae*. Of these 45 phage genomes, 36 are derived from environmental metagenome, so not only is the host unknown but it is not established that any of these phages effect lysis at all. Of the 9 established lytic phages, five have chlamydial hosts, which lack PG and are not relevant to this discussion. The four bacteriolytic phages comprise the *Bdellovibrio* phage phiMH2K, the *Spiroplasma* phage SPV4, and two related phages of *Cellulophaga*, phi12.2 and phi12a.1. In the latter two phages, two proteins of comparable size to *E* with strongly predicted N-out TMDs are encoded, but both have been assigned to be virion proteins, so the identity of the Sgl is a mystery. SPV4 has two small integral membrane proteins but the topology is N-in for both. *Bdellovibrio* phage MH2K encodes a 102 protein with a single N-out TMD; although it has no detectable similarity with *E*, it is an attractive Sgl candidate because, like *E*, it is located in the +1 reading frame of a conserved gene.

The SGLs of the *Leviviridae*

The *Leviviridae* are ssRNA phages with extremely simple genetic organization. They all have three core genes, encoding the essential Mat, Coat, and Rep proteins (Fig. 11). Coat is the major capsid protein that is assembled into a T=3 shell around the ~4 kb RNA; Mat is a ~45 kDa “single molecule tail” that replaces two Coat proteins in the shell. All *Leviviridae* adsorb to a retractable host pilus as the first step in the infection cycle. Most of the genetics and molecular biology studies on *Leviviridae* have been with two phages that recognize the F conjugational pilus: MS2 and Q β . The two phages differ drastically in terms of lysis. MS2 uses a fourth protein, L, encoded in a cistron straddling the *coat-rep* junction, as its Sgl; L-like Sgls are the most common lysis proteins in the diverse *Leviviridae* and will be considered separately below. Q β does not encode a separate lysis gene; instead, lysis is a second function of the Mat protein, which, for historical reasons, is called A₂ in Q β . A₂ has a PA-type mechanism in that it acts as a non-competitive inhibitor of MurA, the conserved enzyme that catalyzes the first step of the PG precursor pathway (Fig. 2). In the MurA catalytic cycle, the two halves of the globular protein close over the catalytic cleft when the two substrates, PEP and UDP-GlcNAc, are bound; genetic and biochemical studies showed that A₂ binds across the cleft after ligand binding, thus locking the enzyme in a stable, inactive form. Recently, cryo-EM studies have revealed the structure of the A₂ protein, mounted on the virion, in complex with MurA; in effect, the Q β particle is the world’s largest enzyme inhibitor.

The Mysterious L

The target of A₂ was identified with the same simple genetic approach used for E: selecting survivors of the induction of the cloned A₂ gene and mapping dominant mutations conferring A₂-resistance to the *murA* locus. In contrast, the target of L has remained a mystery for decades. Indeed, in perhaps the last small triumph of classical phage genetics over genomics, the L gene was not noticed in the published MS2 genome sequence, despite the fact that this was the first genome ever determined and MS2 was known to be a lytic phage. In any case, after nonsense-suppressor analysis revealed that L was the essential lysis gene, many efforts were made to unravel its lytic mechanism. Unlike E and A₂, expression of L does not cause inhibition of net PG biosynthesis, which instead continues unabated until lysis. Moreover, cells undergoing lysis by MS2 infection or by induction of a cloned L gene do not develop the characteristic septal bleb catastrophes. Rigorous mutational and physiological analysis has revealed that L is the prototype of a very diverse family of Sgls, sharing a common domain structure (Fig. 12). L is almost a “mirror-image” of the E Sgl, in that L has a large, dispensable, highly basic N-terminus and an essential, more hydrophobic C-terminus. The N-terminal Domain I confers a requirement for the function of the chaperone DnaJ, strikingly reminiscent of the requirement for SlyD that is conferred by the highly basic E_{CID}. Again, this dependence on a host chaperone may be the key to regulation of lysis under differing physiological conditions. Domain II is extremely hydrophobic but, unlike a traditional transmembrane domain, has positions that are hypersensitive to conservative changes in the side chains. Domain III is the universally conserved dipeptide sequence Leu-Ser, and Domain IV is a species-specific region (Fig. 12).

Although progress has been made in identifying the important parts of L, its target is still mysterious. This is all the more frustrating because leviviral genomics, although ludicrously limited in totaling <100 kb, most of which are male-specific coliphages closely related to MS2 and Q β , indicate that the majority of the ssRNA phages use L-like Sgls. There are only 8 *Leviviridae* phages known outside of the ~30 male-specific coliphages of the MS2 and Q β clans (Table 1). Six of them have L-like Sgl sequences, five of which evolved, like L, at the *coat-rep* junction and the fifth, from *Acinetobacter* phage AP205, at a distinct

Fig. 12 Sgl diversity. Top: L-like Sgls. Domain structure of MS2 L is shown. Missense mutations that abolish lytic function or are without effect are shown above and below the L sequence. Representative L-like Sgls are aligned below the domain diagram. Sources: MS2 and GA (F-specific); HGAL-1 and C1 (IncH and IncC conjugational pili, respectively); AP205 (*Acinetobacter* type IV pilus); PP7 (*Pseudomonas* polar pilus); PRR1 (conjugational pilus of broad host range plasmid RR1). Bottom: PA-type Sgls. N-terminal domain (NTD; light brown) and C-terminal domain (CTD; green) are shown. Sources: ssDNA coliphage ϕ X174 and levivirus M (IncM conjugational pilus). Table 1 The known Levivirus genomes and *sgl* characteristics. All known Levivirus genomes are listed, except for the ~30 relatives of MS2 and Qb. No Sgl has been identified for LeviOR01

Phage	Pilus	Host	Sgl location	Sgl target	Aa
MS2	F	<i>E. coli</i>	coat-rep junction	L-target	75
Q	F	<i>E. coli</i>	A ₂	MurA	420
phiCB5	polar Tad	<i>C. crescentus</i>	middle rep	?	136
PP7	twitching	<i>P. aeruginosa</i>	coat-rep junction	L-target	55
PRR1	IncP-1	<i>P. aeruginosa</i> , others	coat-rep junction	L-target	54
M	IncM	<i>E. coli</i>	distal rep	MurJ	37
Hgal1	IncH	<i>E. coli</i>	coat-rep junction	L-target	65
C-1	IncC	<i>E. coli</i>	coat-rep junction	L-target	65
AP205	twitching	<i>Acinetobacter</i>	5' end	L-target	35
LeviOR01	twitching	<i>P. aeruginosa</i>	?	?	?

Note: Originally published in Chamakura, K., and Young, R., 2019. Phage single-gene lysis: Finding the weak spot in the bacterial cell wall. *Journal of Biological Chemistry* 294, 3350–3358.

site at the 5' end of the gRNA. The other two are phage M, which infects the retractable pilus encoded by IncM plasmids, and CB5, which infects the retractable TAD pili of the marine bacterium (and developmental model system) *C. crescentus*. These two genes encode type I IM proteins with predicted N-out topology like E. Although there is no detectable sequence similarity with E, the Occam's Razor hypothesis would be that both of these Sgls would be MraY inhibitors. This hypothesis was invalidated when it was shown that Lys^M was an inhibitor of MurJ and caused lysis by inhibition of PG biosynthesis (Fig. 2). Indeed, experiments that showed that Lys^M bound MurJ and caused cytoplasmic accumulation of Lipid I, not only settled the target of Lys^M but unambiguously settled the role of MurJ as the long-sought Lipid II flippase.

Nothing has been reported for Lys^{CB5}, but the addition of Lys^M to Qβ A₂ and phiX174 E brings the total number of different PA-type SGLs to 3, each targeting a different step in PG biosynthesis. Considering the diversity of these Sgls, it is a reasonable and exciting hypothesis that any step in the PG biosynthesis pathway, including periplasmic steps, would be a suitable target for a PA-type Sgl. However, after “solving” the CB5 SGL system, which is underway in our laboratory, the sad truth is that there are no more *Leviviridae* with sequenced genomes. Recently some relief from this dismal situation has been brought about by two meta-virome studies revealing a total of ~80 new leviviral sequences. Only one of these genomes had an annotated lysis gene, which turned out to encode an L-like sequence. It will be interesting to see if a rich library of PA-type Sgls can be derived from analysis of these sequences. The first obstacle, of course, is identifying the Sgl in each of these genomes. Considering how small some already identified Sgls are, identifying candidates by genome analysis is going to be problematic. Also, the meta-virome sourcing means that the hosts corresponding to these Sgls are not known, so testing of each Sgl will have to be done in *E. coli* using inducible plasmid systems, with no guarantee that the cognate *E. coli* target will be sensitive to binding and inhibition.

Extrusion

Filamentous phages (*Inoviridae*) produce chronic infections of a culture and release phage progeny by extrusion rather than lysis. The majority of work on filamentous phage has been done on the closely-related *E. coli* Ff phages f1, M13, and fd. These virions have distinct filamentous morphology derived from a single molecule of the circular single-stranded gDNA surrounded in a sheath-like structure made of ~3000 of copies of the major coat protein pVIII. The ends of the filament are made up of minor coat proteins pVII and pIX and pIII and pVI. During replication, all of the structural proteins of Ff phages are targeted to the IM before being assembled in a secretion-like process. Three proteins, pI, pIV, and pXI are not part of the virion structure but form a trans-envelope complex with pI and pXI at the IM and pIV forming a pore-like structure in the OM. In the later stage of infection, positive ssDNA is coated with pV, forming a precursor virion complex with a 32-bp hairpin packaging signal at one end. Genetic analysis indicates that assembly is initiated when the packaging signal interacts with the C-termini of pVII and pIX. The pV-coated ssDNA is brought to the pI-pXI complex and on the cytoplasmic face of the IM. Then pV dissociates from the complex and is replaced by a helical shell of pVIII as the ssDNA is translocated across the IM. Ff assembly requires ATP and the N-terminal region of pI has an essential Walker A motif. Therefore, pI is probably a molecular motor that drives the assembly process. After all of the Ff DNA is covered with pVIII, the filament is released when pVI and pIII bind to the terminal cap of the virion. It is important to note here, although Ff phage do not kill the host cell, they still form plaques. In this case, the clearings are a result of a reduced growth rate that reflects the burden of Ff phage production and secretion on the physiology of infected cells.

Phage Egress in Archaea

The main load-bearing component of the bacterial envelope is the peptidoglycan, so a muralytic enzyme is always a key component of MGL systems. The cell envelope structures of the archaea are extremely diverse and differ from bacteria in profound

ways, chief among which is that, except for a few species of methanogens, archaea lack a load-bearing polysaccharide sacculus. In the methanogens a sacculus is formed from pseudomurein, which resembles bacterial murein in having disaccharide repeating units containing GlcNAc and cross-linking oligopeptides. However, in pseudomurein, the cross-linking oligopeptides contain no D-amino acids and originate in amide links to L-N-acetylalosaminuronic acid rather than MurNAc. Several *Methanobacterium* phages, including the siphophage PsiM2, has been shown to encode and produce an endoisopeptidase (PeiP) that cleaves the epsilon-Ala-Lys isopeptide bond in pseudomurein. Gene *peiP* encodes no secretion signal but is surrounded by five genes that encode proteins with one or more TMDs. The Occam's Razor argument is that one or more of these membrane proteins provide temporally controlled permeabilization of the cytoplasmic membrane, rather than having to invoke a novel secretion mechanism. Whether this mechanism involves holin-like triggering and formation of micron-scale holes in the cytoplasmic membrane remains to be addressed.

As the primary and outer-most component of the envelope, most archaea have S-layers that can not only confer tolerance for extremely harsh conditions but in some cases seem to determine cell shape. Many archaeal viruses appear to conduct chronic infections, released like the bacterial *Inoviridae* by an extrusion process without reducing host viability. Operationally, the extrusion process appears to be similar to the process of extrusion of enveloped viruses in eukaryotes, in which the ESCRT machinery pinches off the viral-containing membrane buds. Even in these cases, release of the virus still requires disruption of the S-layer, by unknown mechanisms. Lytic viruses of the *Crenarchaea* have evolved a spectacular solution for release of the progeny virions, the lysis pyramids. These stunning structures are 7-sided pyramids formed by homo-oligomerization of a single phage protein. When mature, the pyramids protrude through the surface of the cell, penetrating the membrane and dislodging the S-layer array, before opening up to form ~100 nm holes through which the virions are released. These release structures were observed in lytic infections of *Sulfolobus* by the small phages STIV and SIRV2, which are unrelated except for having similar pyramid proteins. One perspective is that in the pleomorphic *Sulfolobus* cells lacking a load-bearing sacculus, there is insufficient osmotic differential between the cytoplasm and the environment to allow explosive events like those effected by MGL.

Extrusion and pyramid-scheme viral release mechanisms would seem to be incompatible with *Caudovirales* structure, and, accordingly no tailed phages have been isolated for the *Crenarchaeota*. However, many phages of the *Euryarchaeota* are *Caudovirales*, comprising all three classic morphologies that are morphologically indistinguishable from their bacterial brethren. In the curated RefSeq database, there are 33 complete genomes of phages of *Euryarchaeota*, of which 20 are *Caudovirales* and two more are *Sphaerolipoviruses*, which are evolutionarily related to the Corticoviruses. All of these phages presumably use lytic mechanisms, rather than extrusion and have been subjected to the evolutionary pressures that led to the development of the complex, multi-step, highly regulated MGL systems in the phages of bacteria. Other than the case of PsiM2, where the presumed MGL-type endolysin has been identified (PeiP), there are no genes related to any lysis gene found in phages of bacteria. Considering that archaea, once thought to be restricted to extreme environmental niches, are now being identified in most environments that have bacteria and may be major players in the ecosystem, it would seem timely to investigate the lysis mechanisms of archaea phages.

Virus Budding

Lara Rheinemann and Wesley I Sundquist, University of Utah, Salt Lake City, UT, United States

Overview

To spread infection, viruses must exit producer cells and transmit their genetic material into target cells. Viruses have evolved two general strategies for cellular egress: (1) Enveloped viruses acquire a host-derived lipid membrane as they breach the limiting membranes of the cell. During this process, the viral membrane typically also acquires one or more viral glycoproteins that bind target cell receptors and facilitate the membrane fusion step required for viral entry. (2) Non-enveloped viruses, by contrast, exit cells when the plasma membrane is disrupted, typically by cell lysis. Non-enveloped viruses then infect target cells either by disrupting limiting membranes to gain access to the cytoplasm or by pumping their nucleic acids directly into the cell. In recent years, the distinction between enveloped and non-enveloped viruses has been blurred by the discovery that some viruses, traditionally thought of as non-enveloped, can exit cells within vesicles. These are termed “quasi-enveloped” viruses.

The process of enveloped virus release comprises a series of coordinated steps, which are illustrated for human immunodeficiency virus type 1 (HIV-1) in **Fig. 1**:

- (1) **Assembly:** Viral proteins and other essential components co-assemble to form virions. Many viruses assemble at the plasma membrane, but others assemble at internal membranes or in the cytoplasm before trafficking to the plasma membrane or exiting via the secretory system.
- (2) **Envelopment:** The host membrane is bent and wrapped around the nascent virion.
- (3) **Budding:** The membrane stalk connecting the virion to the host membrane is constricted and severed to release the enveloped particle.
- (4) **Maturation:** Most enveloped viruses undergo further proteolytic and conformational maturation steps during or after budding. Maturation converts the assembly-competent virion into an infectious virus that can enter, uncoat, and replicate in the new target cell.

The complex series of events that accompany enveloped viral egress must be coordinated spatially and temporally, and these events are typically orchestrated by virally-encoded, multifunctional structural proteins. These proteins bind and remodel the membrane, self-assemble into virions, package other essential components such as nucleic acids into the nascent virion, and contain or recruit all of the activities necessary for budding and maturation. This article will describe general principles of enveloped virus assembly and release using the well-characterized HIV-1 Gag protein as a paradigm for a viral structural protein. Important principles employed by other viral families will also be discussed.

Assembly

All retroviruses, including HIV-1, express a Gag polyprotein that coordinates assembly of the immature virion (Sundquist and Krausslich, 2012; Meng and Lever, 2013; Lingappa *et al.*, 2014). When expressed alone, Gag is released within virus-like particles (VLPs), indicating that it contains or recruits all activities necessary for assembly, envelopment, and budding. An exciting new

Fig. 1 Stages of HIV-1 virion formation. HIV-1 virion formation is coordinated by the multifunctional structural polyprotein Gag. Complexes of Gag with the viral RNA genome (blue) traffic to the plasma membrane where Gag assembles and binds other virion components, including the longer Gag-Pol polyprotein, which contains the viral protease, reverse transcriptase and RNase H enzymes. Gag also recruits three different host factors to facilitate membrane constriction and fission: AMOT-NEDD4L (orange and light purple, respectively), and the early-acting ESCRT-associated factors, ESCRT-I/II (pink) and ALIX (blue), which in turn recruit ESCRT-III proteins (green). ESCRT-III proteins form polymeric filaments that constrict the bud neck with the help of the VPS4 AAA + ATPase and its cofactor LIP5. Protease activation during budding leads to Gag and Gag-Pol processing and formation of the mature, infectious virion.

Fig. 2 The HIV-1 Gag polyprotein. HIV-1 Gag comprises four functional elements connected by two spacer peptides SP1 and SP2 (gray). MA (yellow) facilitates membrane binding and Env incorporation. CA (orange) mediates assembly of the immature capsid and, after proteolytic processing, forms the mature conical capsid. NC (red) binds the viral RNA genome through two zinc finger motifs. p6 (brown) binds Vpr and recruits early-acting ESCRT proteins TSG101 (a subunit of the ESCRT-I complex) and ALIX to facilitate membrane fission. Pink arrowheads denote proteolytic cleavage sites during maturation.

variation on this same theme is the discovery of Gag-related cellular proteins that can self-assemble, exit producer cells, and transfer RNA molecules between cells (Pastuzyn *et al.*, 2018; Ashley *et al.*, 2018).

As illustrated in **Fig. 2**, HIV-1 Gag comprises four functional elements: MA, CA, NC and p6, connected by two spacer peptides: SP1 and SP2. The MA domain in Gag (MA^{Gag}) targets assembly to the plasma membrane, NC^{Gag} binds the dimeric viral RNA genome, the CA^{Gag} and SP1^{Gag} elements mediate spherical particle assembly, and p6^{Gag} recruits cellular ESCRT (Endosomal Sorting Complexes Required for Transport) pathway factors required for virus budding. Gag also packages several other components required for full infectivity, including the viral enzymes, which are packaged as co-assembling Gag-Pol fusion proteins, the viral Env protein, whose intracellular domain interacts with MA^{Gag} , and Viral Protein R (Vpr), which binds p6^{Gag} .

- (1) *RNA packaging*: Following synthesis in the cytoplasm, Gag monomers or low-order multimers bind two associated copies of the full-length viral genomic RNA through a highly structured packaging site located near the 5' end of the genome (Jouvenet *et al.*, 2009; Kutluay and Bieniasz, 2010; Keane *et al.*, 2015). This interaction is mediated by NC^{Gag} and enables specific selection of the HIV-1 genome over cellular RNAs and viral RNAs undergoing translation (Kaddis Maldonado and Parent, 2016; Dubois *et al.*, 2018; Kuzembayeva *et al.*, 2014; Brown *et al.*, 2020). Several host proteins, including ABCE1, Staufen1, and DDX6, can associate with Gag-RNA complexes and have been proposed to promote Gag trafficking, multimerization, and/or genome encapsidation, although these activities are not yet fully defined (Reed *et al.*, 2012; Zimmerman *et al.*, 2002; Chatel-Chaix *et al.*, 2007).
- (2) *Membrane trafficking*: Gag and Gag-RNA complexes move to the plasma membrane and associate with cholesterol-rich microdomains, commonly termed “lipid rafts” (Ono and Freed, 2001). Binding of Gag to the plasma membrane is mediated by a bipartite signal in the MA^{Gag} domain that comprises a post-translational myristic acid modification at the amino-terminus and a cluster of basic residues, the highly basic region (HBR). Prior to membrane binding, the myristate is sequestered in a hydrophobic cavity within the globular MA^{Gag} domain. The HBR interacts with acidic head groups of the plasma membrane-specific phospholipid phosphatidylinositol-(4,5)-bisphosphate ($\text{PI}(4,5)\text{P}_2$) and this interaction, perhaps in concert with Gag multimerization, exposes the myristate moiety. $\text{PI}(4,5)\text{P}_2$ and the conformational “myristoyl switch” enable targeting and stable Gag association with the plasma membrane (Chukkapalli and Ono, 2011; Tang *et al.*, 2004). In addition to $\text{PI}(4,5)\text{P}_2$, MA^{Gag} can also bind cellular RNA, especially tRNAs. The MA-tRNA interactions likely prevent non-specific binding of Gag to cellular membranes other than the plasma membrane (Chukkapalli *et al.*, 2010; Alfadhli *et al.*, 2011; Kutluay *et al.*, 2014; Gaines *et al.*, 2018).
- (3) *Virion assembly*: At the plasma membrane, Gag molecules multimerize and assemble into a hexagonal lattice through lateral protein-protein interactions that are mediated by the CA-SP1 region (Schur *et al.*, 2016; Wagner *et al.*, 2016). Host-derived inositol hexakisphosphate (IP_6) binds within the CA-SP1 hexamers and facilitates formation of the immature Gag lattice (Dick *et al.*, 2018; Mallery *et al.*, 2018). In addition to the genomic RNA, Gag interacts directly with other viral proteins that are incorporated into the nascent virion, including the multifunctional accessory protein Vpr, which binds a leucine-rich element located within p6^{Gag} (Kondo *et al.*, 1995), and the cytoplasmic tail of the gp41 subunit of the heterotrimeric transmembrane Env protein, which is incorporated within holes in the associating Gag lattice created by MA trimerization (Tedbury and Freed, 2014; Tedbury *et al.*, 2016; Hill *et al.*, 1996; Pezeshkian *et al.*, 2019). In addition to the Gag polyprotein, the full-length viral RNA also encodes the Gag-Pol polyprotein. The longer Gag-Pol protein is translated by a ribosomal frameshifting mechanism, contains the viral enzymes, and is incorporated into the nascent virion through interactions with Gag (Smith *et al.*, 1993).

Envelopment

The multifunctional structural proteins that mediate assembly and membrane targeting also appear to facilitate virion envelopment by inducing membrane curvature. The hexagonal HIV-1 Gag lattice contains small discontinuities that accommodate

Table 1 *Viral proteins that mediate assembly and budding of enveloped viruses.* Virus families and species are listed as described in the Virus Taxonomy: 2018b Release by the International Committee on Taxonomy of Viruses (ICTV). To be included in the table, virus families must be enveloped and contain at least one species that infects mammals

<i>Virus family</i>	<i>Example species</i>	<i>Protein(s) mediating assembly and budding</i>
Arenaviridae	Lassa virus, lymphocytic choriomeningitis virus	matrix protein Z
Arteriviridae	Equine arteritis virus, porcine reproductive and respiratory syndrome virus	envelope proteins GP5 and M
Asfarviridae	African swine fever virus	p72 (outer capsid layer), polyproteins pp220 and pp62 (inner core shell)
Bornaviridae	Mammalian 1 orthobornavirus	matrix protein M
Coronaviridae	Middle East respiratory syndrome-related coronavirus, severe acute respiratory syndrome-related coronavirus,	membrane protein M, envelope protein E
Filoviruses	Zaire ebolavirus, Marburg marburgvirus	matrix protein VP40
Flaviviridae	Dengue virus, West Nile virus, Yellow fever virus, hepatitis C virus	envelope proteins prM and E, aided by non-structural proteins
Hantaviridae	Sin Nombre orthohantavirus	envelope proteins Gn and Gc
Hepadnaviridae	Hepatitis B virus	envelope proteins S and L
Herpesviridae	human alphaherpesvirus	Nuclear egress complex (pUL31 and pUL34, primary envelopment), pUL7, pUL51 and other tegument proteins (secondary envelopment)
Matonaviridae	Rubella virus	envelope proteins E1 and E2
Nairoviridae	Crimean-Congo hemorrhagic fever orthonairovirus	envelope proteins Gn and Gc
Orthomyxoviridae	Influenza A virus, influenza B virus	matrix protein M1
Paramyxoviridae	Hendra henipavirus, Nipah henipavirus, measles morbillivirus	matrix protein M
Peribunyaviridae	Bunyamwera orthobunyavirus, La Crosse virus	envelope proteins Gn and Gc
Phenuiviridae	Rift Valley fever virus	envelope proteins Gn and Gc
Pneumoviridae	Human metapneumovirus, human orthopneumovirus	matrix protein M
Poxviridae	Vaccinia virus, variola virus	membrane proteins A14 and A17, scaffold protein D13 and other viral membrane assembly proteins (formation of mature virions); A27, B5, and F13 (formation of enveloped virions)
Rhabdoviridae	Rabies lyssavirus	matrix protein M
Retroviridae	Human immunodeficiency virus-1, human immunodeficiency virus-2,	Gag polyprotein
Tobnaviridae	Equine torovirus, porcine torovirus	membrane protein M
Togaviridae	Chikungunya virus, eastern equine encephalitis virus	envelope proteins E1 and E2

declination and allow the immature lattice to bend the membrane and create a spherical virion (Schur *et al.*, 2016). The host factor angiomin (AMOT) has also been implicated in HIV-1 virion envelopment because fully enveloped spherical particles are not formed efficiently in the absence of AMOT (Mercenne *et al.*, 2015). The Bar domain of AMOT likely contributes to this activity as this domain has been shown to bend and tubulate membranes in other contexts (Nishimura *et al.*, 2018).

Unlike HIV-1, betaretroviruses and spumaviruses assemble in the cytoplasm before being trafficked to the plasma membrane. Thus, assembly and budding are spatially and temporally separated in these viruses. For example, Gag proteins from prototypal foamy virus, Mason-Pfizer monkey virus, and mouse mammary tumor virus preassemble into immature virions near the pericentriolar region and are then trafficked on microtubules to associate with membranes and the viral Env protein (Müllers, 2013; Hütter *et al.*, 2013; Swanstrom and Wills, 1997). Hepatitis B virus (HBV), a hepadnavirus, similarly forms capsids in the cytoplasm, which then associate with envelope proteins in cellular membranes to mediate particle envelopment and budding (Prange, 2012; Blondot *et al.*, 2016).

More broadly, most enveloped viruses have multifunctional structural proteins that mediate assembly and envelopment. Often, this role is fulfilled by matrix proteins that bind to the viral membrane, assemble into higher-order structures, and link internal ribonucleoprotein complexes to external envelope glycoproteins. In viruses that lack classical matrix proteins, such as hantaviruses (Hepojoki *et al.*, 2012; Cifuentes-Munoz *et al.*, 2014; Muyangwa *et al.*, 2015) and alphaviruses (Brown *et al.*, 2018), cytoplasmic tails of envelope glycoproteins act as matrix protein surrogates by directly interacting with nucleoproteins. Larger, more complex DNA viruses such as pox viruses (Roberts and Smith, 2008; Liu *et al.*, 2014) and herpes viruses (Lv *et al.*, 2019) divide these functions between multiple viral proteins (see Table 1).

Budding

ESCRT-dependent budding

As membrane envelopment proceeds, the membrane is constricted until nascent virions are connected to the plasma membrane by a thin stalk that must be severed to separate the viral and cellular membranes. Many enveloped viruses accomplish membrane constriction and fission by recruiting the machinery of the cellular ESCRT pathway (Votteler and Sundquist, 2013).

ESCRT-independent enveloped viruses also exist, however, and these viruses must therefore either recruit other, as yet unidentified, host factors or encode viral proteins that mediate budding.

The ESCRT pathway mediates cellular membrane fission events throughout eukarya and also in some archaeal species (McCullough *et al.*, 2018; Christ *et al.*, 2017; Scourfield and Martin-Serrano, 2017; Henne *et al.*, 2013). The pathway was initially identified as the machinery that mediates intraluminal vesicle budding into specialized late endosomes, termed multivesicular bodies (MVB) (Hanson and Cashikar, 2012), but is now known to act at many other cellular membranes, including during cytokinetic abscission (Carlton and Martin-Serrano, 2007; Morita *et al.*, 2007), resealing of the post-mitotic nuclear envelope (Olmos *et al.*, 2015; Vietri *et al.*, 2015), membrane repair (Scheffer *et al.*, 2014; Jimenez *et al.*, 2014; Skowrya *et al.*, 2018), closure of autophagosomes (Takahashi *et al.*, 2018; Zhou *et al.*, 2019), and neuronal pruning (Zhang *et al.*, 2014; Loncle *et al.*, 2015; Issman-Zecharya and Schuldiner, 2014). Notably, all of these membrane fission events involve constricting membranes toward a cytoplasm-filled neck and are therefore topologically equivalent to virus budding from the plasma membrane.

ESCRT-mediated membrane fission events are catalyzed by a common core machinery (McCullough *et al.*, 2018; Christ *et al.*, 2017; Scourfield and Martin-Serrano, 2017; Banjade *et al.*, 2019), which is recruited to different membranes by adapter proteins. These membrane-specific adapters recruit early-acting ESCRT proteins, which help to stabilize membrane curvature and also nucleate assembly of late-acting ESCRT-III proteins, which form the core fission machinery. ESCRT-III proteins can be recruited by three known mechanisms: (1) Adapters can recruit Bro1 domain-containing proteins such as ALIX, which serves as a bridge to the ESCRT-III proteins, (2) Adapters can bind the ESCRT-I complex, which in turn recruits ESCRT-III proteins via intermediate ESCRT-II complexes, and (3) The nuclear LEM2 adapter binds CHMP7, a hybrid ESCRT-II/ESCRT-III protein, which then binds other ESCRT-III proteins.

Humans express 12 related ESCRT-III proteins that are divided into eight subfamilies, CHMP1–7 and IST1, with some subfamilies comprising several homologs. ESCRT-III proteins can adopt “closed” and “open” conformations. In the autoinhibited closed state, ESCRT-III proteins are soluble and monomeric. When autoinhibition is relieved, ESCRT-III subunits open and can then bind membranes and form curved helical filaments. These filaments constrict membranes and recruit VPS4 AAA + ATPases. VPS4 enzymes dynamically remodel and disassemble ESCRT-III filaments, using the energy of ATP hydrolysis to extract individual ESCRT-III subunits and release them back into the cytoplasm. These enzymes thereby power the virus budding cycle, although the precise mechanism by which ESCRT-III filaments and VPS4 enzymes collaborate to mediate fission is not yet fully understood.

Enveloped viral structural proteins recruit the ESCRT pathway using motifs that mimic cellular ESCRT adapters (Votteler and Sundquist, 2013; Hurley and Cada, 2018; Lippincott-Schwartz *et al.*, 2017). These motifs were initially discovered in retroviral Gag proteins (Gottlinger *et al.*, 1991; Huang *et al.*, 1995; Parent *et al.*, 1995; Xiang *et al.*, 1996) and were termed “late domains” because they exerted their effects at a late stage of assembly. Analogous late domains were subsequently identified in many other enveloped viruses. Late domains can frequently function from different positions within viral structural proteins and can be swapped between viruses (Parent *et al.*, 1995; Yuan *et al.*, 2000), consistent with the idea that although they have different primary binding partners, they all ultimately converge on common downstream ESCRT-III proteins. Several different classes of late domains are now well understood, and others have been identified but remain to be linked to ESCRT binding partners.

P(S/T)AP: The P(S/T)AP late domain (where the second residue can be either a serine or a threonine) was first identified in the p6 polypeptide of HIV-1 Gag (Gottlinger *et al.*, 1991; Huang *et al.*, 1995), and subsequently identified in structural proteins of other retroviruses, filoviruses, arenaviruses and reoviruses (Votteler and Sundquist, 2013). The P(S/T)AP motif recruits the four-protein ESCRT-I complex by binding the UEV domain of the TSG101 subunit (Demirov *et al.*, 2002; Garrus *et al.*, 2001; VerPlank *et al.*, 2001; Martin-Serrano *et al.*, 2001). P(S/T)AP motifs are found in several cellular ESCRT adapter proteins, such as the early endosomal protein HRS (Bache *et al.*, 2003).

YPX_nL: YPX_nL late domains (where X_n can vary in sequence and length) recruit ALIX by binding the central V domain (Strack *et al.*, 2003; Martin-Serrano *et al.*, 2003; von Schwedler *et al.*, 2003). HIV-1 contains a YPX_nL late domain, although this motif is less critical for budding than the PTAP motif in most cell types. Other viruses rely exclusively or primarily on YPX_nL domains for budding, including other retroviruses, paramyxoviruses, flaviviruses, and possibly herpesviruses (Votteler and Sundquist, 2013). Divergent structural proteins that lack a readily detectable YPX_nL motif, yet still bind to ALIX, have also been described (Boonyaratanakornkit *et al.*, 2013; Lee *et al.*, 2012), suggesting that ALIX-recruiting sequence motifs may accommodate more variability than has been documented to date. Cellular YPX_nL-containing ESCRT adapters recruit ALIX during exosome biogenesis and lysosomal sorting (Baietti *et al.*, 2012; Dores *et al.*, 2012).

PPXY: The PPXY late domain (where X can be any residue but is often a proline) binds WW domains in NEDD4-like HECT ubiquitin E3 ligases. PPXY late domains are found in retroviruses, filoviruses, arenaviruses, rhabdoviruses, and hepadnaviruses (Votteler and Sundquist, 2013). HIV-1 Gag does not contain a recognized PPXY motif. Nevertheless, overexpression of the ubiquitin E3 ligase NEDD4L induces budding of HIV-1 Gag constructs that lack PTAP and YPX_nL late domains (Usami *et al.*, 2008; Chung *et al.*, 2008). In this context, NEDD4L is recruited by a cellular PPXY-containing protein AMOT, which also binds HIV-1 Gag (Mercenne *et al.*, 2015). The related angiomin-like 1 (AMOTL-1) recruits NEDD4 family members to paramyxovirus M proteins, which also lack discernible PPXY domains (Pei *et al.*, 2010; Ray *et al.*, 2019). NEDD4 E3 enzymes transfer K63-linked ubiquitin chains onto PPXY-containing cellular proteins, and they regulate endocytosis, ESCRT-dependent MVB cargo selection and protein trafficking through ubiquitination (Rotin and Kumar, 2009).

It is not yet fully understood how NEDD4 family members promote budding, but it has been suggested that ubiquitination of viral structural proteins, or other proteins within the budding site, recruits the ESCRT pathway because ALIX and TSG101 both contain ubiquitin-binding domains that can recognize ubiquitinated cargos for MVB incorporation and lysosomal degradation

(Shields and Piper, 2011). Consistent with this idea, retroviral Gag proteins are typically ubiquitinated (although this requirement is not absolute (Zhadina *et al.*, 2007)), and ubiquitin depletion or mutations that prevent ubiquitin ligase recruitment inhibit retrovirus budding (Patnaik *et al.*, 2000; Strack *et al.*, 2000).

FPIV: The paramyxovirus SV5 employs an FPIV motif to facilitate budding. SV5 release is ESCRT-dependent and is augmented by AMOTL1, but the binding partner for the FPIV motif remains to be defined (El Najjar *et al.*, 2014).

Viral structural proteins typically encode multiple late domains that function in synergy. For example, HIV-1 p6^{Gag} contains both a P (S/T)AP and a YPX_nL motif, the HTLV-I Gag and Ebola virus (EBOV) structural protein VP40 proteins contain adjacent PPPY and PTAP late domains that bind both TSG101 and NEDD4, and murine leukemia virus Gag contains all three canonical late domains (Votteler and Sundquist, 2013). Nevertheless, some viruses contain a single (or at least dominant), late domain. For example, the retroviral EIAV Gag protein appears to recruit ALIX exclusively through a single YPX_nL motif (Votteler and Sundquist, 2013).

All modes of viral ESCRT pathway recruitment ultimately converge on ESCRT-III, the machinery that catalyzes membrane fission. In the best-studied cases such as HIV-1, multiple different mammalian ESCRT-III proteins have been shown to localize to the bud neck (Jouvenet *et al.*, 2011), but only CHMP2 and CHMP4 family members seem to perform indispensable functional roles (Sandrin and Sundquist, 2013; Morita *et al.*, 2011). ESCRT-III proteins form helical filaments in the bud neck and progressively constrict it with the help of VPS4 enzymes, as described above. Ultimately, a membrane fission reaction severs the neck, releasing the virion from the cell.

ESCRT-independent budding

Some enveloped viruses bud independently of the ESCRT pathway, including alphaviruses (Brown *et al.*, 2018), some paramyxoviruses (Salditt *et al.*, 2010; Utley *et al.*, 2008), and influenza A virus (Rossman and Lamb, 2011). ESCRT-independent membrane scission mechanisms are generally not well understood, but appear to involve as yet unidentified cellular factors, virally encoded proteins, or a combination.

Some RNA viruses, such as alphaviruses, contain an outer glycoprotein shell that completely covers the exterior of the viral membrane. The formation of this external protein coat has been suggested to play a role in virus budding, both in ESCRT-independent and ESCRT-dependent viruses. The alphaviral transmembrane glycoproteins E1 and E2 are embedded in the viral lipid envelope and form heterodimers that further trimerize into a continuous icosahedral lattice. These interactions are required to complete the budding step, and completion of the E1-E2 protein lattice, together with the nucleocapsid interactions across the viral membrane may be sufficient to drive both membrane curvature and fission (Brown *et al.*, 2018; Weissenhorn *et al.*, 2013). In contrast, flaviviruses and hepaciviruses also contain an outer protein coat, but still depend on the ESCRT pathway to complete their replication cycle (see below). Thus, external protein coats can apparently either replace or act in concert with the ESCRT pathway.

Influenza A is another ESCRT-independent virus (Bruce *et al.*, 2009; Watanabe and Lamb, 2010; Chen *et al.*, 2007), but in this case, the viral transmembrane protein M2 appears to mediate membrane fission (Rossman *et al.*, 2010). During particle assembly, the hemagglutinin (HA) and neuraminidase (NA) glycoproteins are targeted to the plasma membrane and cluster in lipid rafts. The matrix protein M1 interacts with the cytoplasmic tails of HA and NA, polymerizes against the membrane, and apparently acts in concert with HA to induce membrane curvature. M1 also recruits M2 to the bud neck, and an amphipathic helix in the cytoplasmic M2 tail inserts, deforms and promotes plasma membrane fission (Martyna and Rossman, 2014; Chlanda and Zimmerberg, 2016). M2 also functions as a pH-regulated ion channel that facilitates the release of viral ribonucleoprotein complexes from the endosome into the cytoplasm, but ion channel and membrane fission appear to be independent activities (Rossman *et al.*, 2010).

Intracellular budding

Some viral families envelop and bud into internal cellular membranes rather than at the plasma membrane. Budding into the lumen of a cellular organelle is topologically equivalent to budding from the plasma membrane, but in these cases the viral particle is temporarily surrounded by two membranes, the viral envelope and the organelle membrane. Virion release into the extracellular space therefore requires transport to and fusion of the virion-containing organelle with the plasma membrane.

One such case is the hepatitis B virus (HBV), which co-opts the MVB pathway for egress (Prange, 2012; Blondot *et al.*, 2016; Patient *et al.*, 2009). The three viral envelope proteins S, M, and L form budding sites at the MVB membrane that recruit mature cytoplasmic nucleocapsids. The assembling HBV particles bud into the MVB lumen in an ESCRT-dependent reaction that creates intraluminal virions. MVBs then fuse with the plasma membrane to release the enveloped viral particles from the cell, a process that resembles exosome release.

Herpesviruses are released via the secretory pathway in a complex series of events that requires several viral and cellular proteins (Lv *et al.*, 2019; Fradkin and Budnik, 2016; Owen *et al.*, 2015). Herpesviral genome replication, capsid assembly, and genome packaging all take place in the nucleus. The fully assembled nucleocapsids are too large to escape into the cytoplasm through nuclear pores and instead exit the nucleus and cell by undergoing several steps of envelopment and de-envelopment at multiple cellular membranes. During primary envelopment, the nucleocapsids bud through the inner nuclear membrane into the perinuclear space, thereby acquiring a lipid envelope. This process requires the virus to remodel the nuclear lamina. Cellular and viral kinases phosphorylate components of the nuclear lamina, leading to its disassembly. Two viral proteins, pUL31 and pUL34, then assemble into a cage-like nuclear egress complex, that carries the virion across the inner nuclear membrane (Bigalke and Heldwein, 2015). There is some evidence that the ESCRT machinery may also be involved in facilitating the membrane fission step required

to release the enveloped virion into the intermembrane space (Arii *et al.*, 2018). The primary envelope then fuses with the outer nuclear membrane in a process termed de-envelopment. The viral glycoproteins are necessary for de-envelopment, likely because they mediate fusion with the outer nuclear membrane. Once in the cytoplasm, nucleocapsids associate with tegument proteins, which in the mature virion occupy the space between the nucleocapsid and the envelope. The nucleocapsids then bud into vesicles, whose origins have been variously described as the trans-Golgi network, endosomes, or autophagic membranes. Recruitment to sites of secondary envelopment is promoted by tegument proteins through interactions with vesicle membranes and viral glycoproteins. Early-acting ESCRT proteins are not required for this process, but there are reports that ESCRT-III and VPS4 activity are required for virion release (Crump *et al.*, 2007; Calistri *et al.*, 2007; Pawliczek and Crump, 2009), and an exciting new structure of the herpes simplex virus pUL7: pUL51 complex, which is required for efficient virion assembly, reveals that the N-terminal region of pUL51 adopts a CHMP4B-like fold that may function as a viral ESCRT-III-like protein (Butt *et al.*, 2020). Following membrane fission, the enveloped virions end up inside intracellular vesicles and are released into the extracellular space when the vesicles fuse with the plasma membrane.

In a related process, flaviviruses and hepaciviruses are released through the secretory pathway (Chatel-Chaix and Bartenschlager, 2014; Falcon *et al.*, 2017; Gerold *et al.*, 2017). Both genera of viruses induce extensive remodeling of endoplasmic reticulum (ER) membranes to form replication compartments. These vesicle-like structures remain connected to the ER, enclose viral proteins and the viral genome, and serve as protected compartments where almost all steps of the life cycle are carried out. Assembled nucleocapsids then bud into the ER lumen and are released through the secretory pathway.

Quasi-enveloped viruses

Historically, viruses have been divided into enveloped and non-enveloped classes based on the presence or absence of a host-derived membrane envelope, and it was thought that non-enveloped viruses were released exclusively by host cell lysis. This simple paradigm has now been overturned by studies showing that many different classes of non-enveloped viruses can acquire host-derived lipid envelopes and exit cells within vesicles. These extracellular vesicles resemble exosomes, and viruses that use this egress method are termed “quasi-enveloped” (Feng *et al.*, 2014).

The picornavirus hepatitis A virus (HAV) was the first virus definitively shown to be quasi-enveloped (Feng *et al.*, 2013), and HAV still serves as a paradigm for the process. Quasi-enveloped HAV particles (eHAV) are released in exosome-like vesicles that typically contain 1–4 particles per vesicle. These vesicles are formed when HAV capsids bud into endosomes in an ESCRT-dependent manner. To promote budding, the VP2 capsid protein recruits ALIX, apparently using tandem YPX₃L domains that become buried in the fully assembled virion (Gonzalez-Lopez *et al.*, 2018; McKnight *et al.*, 2017). Virion-containing multivesicular bodies then fuse with the plasma membrane and release eHAV particles into the extracellular space. There is now good evidence that this is the primary mode of HAV release from hepatocytes *in vivo*, and that HAV circulates in the blood exclusively within small vesicles (Feng *et al.*, 2013). HAV can then shed its envelope in the biliary tract, which produces a non-enveloped particle that may be more stable in harsher environmental conditions (Feng *et al.*, 2014). Importantly, HAV is highly infectious in both its enveloped and non-enveloped states.

The capacity for quasi-envelopment has since been described for several other viruses that were traditionally considered to be non-enveloped, including many other picornaviruses (Chen *et al.*, 2015; Mutsafi and Altan-Bonnet, 2018), Hepatitis E virus (Qi *et al.*, 2015), rotaviruses and noroviruses (Santiana *et al.*, 2018). Furthermore, some picornaviruses, including poliovirus and coxsackievirus, differ from the HAV paradigm in that they form quasi-enveloped virions by subverting the autophagy pathway. In these cases, double-membraned autophagosomes engulf multiple naked viral particles, which then release quasi-enveloped viruses when the outer autophagosomal membrane fuses with the plasma membrane (Mutsafi and Altan-Bonnet, 2018; Bird *et al.*, 2014). A final variation on this theme is the exosomal transfer of viral nucleic acids between cells, which apparently can, in some viruses like hepatitis C, spread productive infections without requiring full viral assembly (Ramakrishnaiah *et al.*, 2013; Bukong *et al.*, 2014).

The membrane appears to perform several important functions for quasi-enveloped viruses, including protecting the capsid from antibody-mediated neutralization (Feng *et al.*, 2013), and clustering together of multiple virions so that they can enter target cells as a swarm or “quasi-species” that can cooperate genetically through cross-complementation. The later activity may be most important for enteroviruses, whose larger vesicles can each contain tens or even hundreds of viral particles (Chen *et al.*, 2015; Santiana *et al.*, 2018).

The outer membranes of quasi-enveloped viruses lack viral glycoproteins, and therefore cannot fuse with target cell membranes. Instead, eHAV particles are taken up into the host cells by endocytosis and trafficked toward the lysosome, where the membrane is degraded, and the released naked virions can cross into the cytoplasm by disrupting the endolysosomal membrane (Rivera-Serrano *et al.*, 2019).

Maturation

Most enveloped viruses undergo additional maturation steps during and after budding. Before maturation, the virion functions as an assembly machinery that can package components and leave the producer cell. Conformational changes, typically triggered by proteolytic cleavage or pH changes, then convert the virion into a particle that is capable of entering and replicating in a new target cell (Veesler and Johnson, 2012; Steven *et al.*, 2005).

In the case of HIV-1, the viral protease (PR) is activated by autoproteolysis as the virus assembles and buds, and it cleaves the Gag polyprotein at five different sites, producing three new proteins (MA, CA and NC) and three smaller peptides (SP1, SP2, and p6). Gag processing drives a series of major rearrangements in which the CA protein forms a conical internal capsid that surrounds viral RNA in complex with NC protein and viral enzymes. Gag cleavage is a sequential, ordered process, and each processing event appears to perform a different function. Cleavage at the SP1-NC junction releases the NC-RNA complex to condense to the center of the virion, cleavage at the MA-CA junction promotes folding of the CA N-terminus into a β -hairpin that will ultimately form an NTP-permeable pore in the assembled capsid, and cleavage at the CA-SP1 junction destabilizes the immature lattice and promotes formation of the mature capsid lattice. The NC-SP2 and SP2-p6 cleavages are also required for infectivity, as is cleavage of the longer Gag-Pol polyprotein, which liberates the viral enzymes. The mature conical capsid is a fullerene cone, with a curved hexagonal lattice comprising CA hexamers, and the cone ends closed through the incorporation of 12 CA pentamers. CA hexamers are stabilized by binding IP₆ (Dick *et al.*, 2018; Mallery *et al.*, 2018), and differential placement of the hexamers and pentamers produces a variety of related capsid structures that each differ slightly in length and shape (Sundquist and Krausslich, 2012; Mattei *et al.*, 2016; Freed, 2015).

Viral glycoproteins and their fusion peptides that enable entry into target cells must also typically be proteolytically processed to be functional. For example, the HIV-1 Env glycoprotein is synthesized as a polyprotein precursor (gp160), which is inserted into the endoplasmic reticulum membrane co-translationally. Env is glycosylated and then proteolytically cleaved by the host Golgi-associated protease furin as it traffics through the secretory pathway, producing the mature surface gp120 and transmembrane gp41 glycoprotein subunits, which remain non-covalently associated as heterotrimeric spikes. Proteolytic processing exposes the fusion peptide at the gp41 N-terminus and is required for fusogenic activity (Checkley *et al.*, 2011).

In other viruses, proteolytic activation of viral fusion proteins can occur following entry into the target cell. Activation of the EBOV glycoprotein is a particularly well-understood case. EBOV particles associate with the host cell surface by interactions with host receptors that bind to glycans on the viral glycoprotein GP and phosphatidylserine in the viral envelope. After internalization through macropinocytosis, endosomal cysteine proteases such as cathepsins L and B proteolytically process GP to remove a mucin-like subdomain and the glycan cap and expose the receptor-binding site (RBS). The RBS binds the late endosomal/lysosomal protein NPC1, which induces a conformational change in GP, insertion of a fusion loop into the endosomal membrane, fusion of viral and endosomal membranes and release of the nucleocapsid into the cytoplasm (Lee and Saphire, 2009; Carette *et al.*, 2011; Cote *et al.*, 2011; Gong *et al.*, 2016; Wang *et al.*, 2016).

Cell-to-Cell Transmission

After budding, viruses can spread in two different ways; through cell-free transmission and cell-to-cell transmission. Cell-free virions diffuse freely through the extracellular space, and even between organisms, before entering target cells. This process can promote dissemination over long distances, to new tissues, and between hosts. However, untargeted diffusion through aqueous media is relatively inefficient, and free viruses are susceptible to immune recognition. In contrast, viral spread through direct sites of cell-to-cell contact increases transmission efficiency and can help evade antibody recognition. To promote cell-to-cell transmission, viruses often subvert cellular structures that are normally used for cell-cell communication or cargo transfer.

Retroviruses such as HIV-1 and MLV actively promote the formation of adhesive structures between donor and target cells. These stable contact sites are termed virological synapses because they resemble the immunological synapses that mediate antigen presentation, and even employ some of the same molecular components. Virological synapse formation requires interactions between the viral glycoprotein on the donor cell and its cognate target cell receptor. Coreceptors and adhesion molecules are then recruited to stabilize and further organize these contact sites, and the producer cell cytoskeleton is repolarized towards the synapse to promote directional viral assembly and release. Virions bud directly into the intersynaptic space and are transferred efficiently to the closely opposed target cell (Agosto *et al.*, 2015; Bracq *et al.*, 2018; Dufloo *et al.*, 2018; Nejmeddine and Bangham, 2010).

Other viruses hijack existing cell-cell contacts for transmission. For example, neurotropic viruses such as herpesviruses and rabies viruses are transported along axons and spread across synaptic contacts (Koyuncu *et al.*, 2013). Viruses can also achieve targeted release by exploiting membrane protrusions such as nanotubes and filopodia, which normally transmit information and cargoes between cells (Agosto *et al.*, 2015; Bracq *et al.*, 2018; Dufloo *et al.*, 2018).

Conclusions

The principles of enveloped virus budding are remarkably conserved between different virus families, presumably owing to evolutionary history and common functional requirements. Viral egress is typically orchestrated by multifunctional structural proteins that recruit components, assemble the virion, bend host membranes, and facilitate membrane fission. In many, but not all cases, the cellular ESCRT pathway is recruited to mediate the final membrane fission step. Recent studies have also revealed that many traditional “non-enveloped” viruses can be released within vesicles as quasi-enveloped viruses and that viruses frequently alter cellular pathways to promote directional release and synapse formation.

Although the general strategies for enveloped virus egress are increasingly well understood, important challenges remain, including characterizing the release mechanisms of ESCRT-independent viruses, the biology and entry mechanisms of quasi-enveloped viruses, and the molecular mechanisms and pathogenesis associated with cell-to-cell viral spread. These and other

advances will help reveal the best approaches for inhibiting virus release for therapeutic benefit and harnessing release activities in new systems that can be used to deliver biomolecular cargoes into target cells in vivo.

Acknowledgments

We thank Moona Huttunen and Jörg Votteler for helpful comments on the manuscript, and Janet Iwasa for creating the figures. This work was funded by NIH R37 AI051174. We apologize to our many colleagues whose primary literature references we were unable to cite owing to space limitations.

Glossary

Apical membrane Surface of the plasma membrane of polarized cells that faces inward to the lumen.

Autophagy A highly regulated process by which cytoplasmic contents become engulfed in membranes resulting in a double-membrane vesicle (autophagosome) that fuses with lysosomes for degradation of its cargo.

Basolateral membrane Surface of the plasma membrane that faces towards the interstitium and forms the basal and lateral sides of polarized cells.

Caveolae Microdomains of the plasma membrane characterized by invaginations of the lipid bilayer in a flask-like structure that is involved in endocytosis and signal transduction pathways.

Cell Polarity Asymmetric organization of cellular components including its plasma membrane, cytoskeleton, and/or organelles into functionally specialized domains. For epithelial and endothelial cells, this usually reflects polarization across the apical-basal axis.

Clathrin-coated pits Regions of the plasma membrane coated with clathrin on its cytoplasmic surface involved in receptor-mediated endocytosis and vesicle transport.

Dynamin Enzyme responsible for pinching off the cargo-loaded vesicles from the parent membrane during the early stages of endocytosis.

Endocytosis Process of cellular internalization of molecules through budding of vesicles derived from the plasma membrane into the cytoplasm.

Endothelial cell Cells that line the interior surface of all blood and lymphatic vessels.

Epithelial cell Cells that line the surface and cavities of tissues and organs and are involved in protection, absorption, secretion, and intercellular transport of molecules.

ESCRT Endosomal complexes required for transport, a series of multiprotein complexes that sort cargo for loading

into multivesicular endosomes (MVE), and mediate membrane abscission events in MVE and autophagosome formation.

Exocyst Octameric protein complex that mediates the tethering of secretory vesicles to the plasma membrane prior to fusion and release of cargo.

Exocytosis Process of release of material from the cytoplasm to the extracellular space mediated by intracellular vesicles.

Exosome A small (50–150 nm diameter) extracellular vesicle that shuttles protein or RNA cargo between cells and contributes to important intercellular communications and that originates within multivesicular endosomes.

Intraluminal vesicle (ILV) A cargo-laden vesicle located within a multivesicular endosome.

Macropinocytosis Actin-dependent type of endocytosis involved in the non-selective engulfment of macromolecules.

Microvesicle Large extracellular vesicle (> 150 nm diameter) shed from the plasma membrane of cells.

Multivesicular endosome (MVE) A large endosome containing multiple intraluminal vesicles (ILV) slated either for delivery to lysosomes for degradation or export as exosomes.

Polymeric immunoglobulin receptor (pIgR) Receptor that mediates the transcytosis of the soluble dimeric immunoglobulin A isoforms and immune complexes from the basolateral to the apical cell surface.

Retrotranscytosis Apical-to-basolateral retrograde transport of secretory immunoglobulin-antigen complexes from the lumen to the subepithelial space.

Transcytosis Vectorial transport of molecules enclosed within membrane-bound vesicles from one side of a polarized cell to the other.

Introduction

The transport of viruses through cells in membrane-limited vesicles plays an important role in many viral infections. Transcytosis describes the vectorial intracellular transport of macro- and micro-molecules (*i.e.*, cargo) within membrane-bound vesicles from one side of a polarized cell to the other (**Fig. 1**, left). The existence of this directional process of intracellular trafficking was first postulated by George Palade in the 1950s, but it was not until the late 1970s that the term ‘transcytosis’ was coined (**Tuma and Hubbard, 2003**). The identification of caveolae, originally termed ‘plasmalemma vesicles’, around the same time represented an important discovery that provided a mechanistic explanation for the movement of cargo through layers of cells in situations where there was minimal paracellular permeability. While these and other early studies described this phenomenon almost exclusively in endothelial cells lining the inner surface of the microvasculature, it is now known to occur in a variety of other polarized cell types.

From a cellular point of view, viruses undergoing transcytosis can be considered as macromolecular cargo capable of hijacking this normal mechanism of vesicular transport given the correct cues and context. From the virus point of view,

Fig. 1 Membrane topology in vesicle-mediated transcytosis and export of viruses. Transcytosis is displayed on the left. Viruses are internalized through endocytosis, transported intracellularly in membrane-bound vesicles, and secreted towards the extracellular space on the opposite side of a polarized cell. Traffic can be in either direction. Vesicle-mediated virus release is shown on the right. Newly assembling virus particles are recruited to and bud into endosomal membranes, forming multivesicular endosomes, or become engulfed in double-membrane autophagosomes. Fusion of the outer membrane of these transport vesicles with the plasma membrane results in the extracellular release of vesicles containing viral capsids.

transcytosis represents an elegant mechanism for crossing physical barriers that normally provide an important intrinsic defense mechanism. Transcytosis has been documented not only for mammalian viruses, but also for invertebrate viruses such as those that need to cross the midgut of insects. Re-purposing this method of directional transport to facilitate invasion of the host offers several advantages, including the potential for a lack of dependence on specific cellular receptors and limiting the induction of signals capable of triggering innate immune antiviral responses. By definition, transcytosis does not result in productive infection of the involved cell. Nonetheless, by allowing viruses to traverse barriers posed by layers of protective epithelial cells to reach specific permissive types of cells supporting replication, transcytosis may be critical for virus spread within the host, pathogenesis, and viral transmission.

Certain viruses also usurp cellular mechanisms of vesicle-mediated transport to facilitate their release from cells. This form of viral egress is becoming increasingly recognized among viruses that are canonically considered to be nonenveloped but that are released from cells in the absence of cell lysis. It is best characterized for hepatitis A virus (HAV) and enteroviruses, both members of the picornavirus family, and hepatitis E virus (HEV), an unrelated positive-strand RNA virus. Newly assembled progeny virions either bud into endosomes, forming intraluminal vesicles within multivesicular endosomes, or are engulfed in autophagosomes, in both cases resulting in multi-layered vesicles that traffic to the plasma membrane where fusion of the outer membrane and plasma membrane discharges their contents and results in the release of virus within extracellular vesicles (Fig. 1, right). While sharing in common with transcytosis several features of vesicle-mediated transport, including the involvement of Rab-GTPases facilitating directional transport of virus-containing vesicles within cells and possibly also mechanisms of vesicle fusion at the plasma membrane, there are fundamental differences and different molecular machinery involved in these pathways.

Transcytosis

Transcytosis can be divided into three general steps: (1) the internalization of virus on one side of a polarized cell within a membrane-bound vesicle, (2) directional transport of the cargo-laden vesicle across the cell, and (3) release of the vesicle contents towards the extracellular space on the opposite side of the cell (Tuma and Hubbard, 2003) (Fig. 1, left). The first step in transcytosis of viruses commonly involves their endocytic uptake through invaginations of the plasma membrane in the form of clathrin-coated pits, caveolae, or macropinosomes. Once the virions have been internalized within membrane-bound vesicles, the second step requires the proper sorting and transport of these virion-loaded vesicles to the opposing side of the cell rather than, for example, endosomal recycling or a degradative lysosomal pathway. The final step involves release of the intraluminal contents of the vesicles to the extracellular space on the opposite side of the cell. Several signaling cues are required for this highly coordinated process to occur, and many aspects of it are not understood. Transcytosis requires cells to be highly polarized in nature, typically

Fig. 2 Experimental set-up to study viral transcytosis in cell culture. Culture cells are grown at high confluency on a semi-permeable membrane and allowed to form a tight monolayer and establish polarity. For studying apical-to-basolateral viral transcytosis, virus inoculum is added to the media bathing the top of the cell monolayer (apical chamber). For basolateral-to-apical transcytosis, the virus inoculum is added to the basal chamber. Apical and basolateral fluids are collected at specific times post-infection and viral titers are measured. The integrity of the monolayer must be assessed throughout the experiment by measuring transepithelial electrical resistance or paracellular diffusion of marker molecules to ensure transcytotic movement.

across an apical-basal axis, and it is thus restricted to specific cell types. While most commonly studied in endothelial and epithelial cells, transcytosis occurs in other types of polarized cells, including hepatocytes and syncytiotrophoblasts of the placenta.

***In vitro* Models of Viral Transcytosis**

Cell culture models have been used widely to recapitulate transcytosis in the context of a viral infection. These systems can be conditionally manipulated to study effects of environment or genetic factors on the efficiency and kinetics of directional virus transport across cells. Most frequently used is the 'Transwell' assay that involves use of a nonpermeable monolayer of epithelial cells grown on a porous surface as substratum, with media bathing both sides of the cells to promote cell polarity (**Fig. 2**) (**Oztan et al., 2008**). A wide array of different porous materials (*e.g.*, polycarbonate, polystyrene, polyethylene-terephthalate) with distinct pore sizes and coatings that mimic the extracellular matrix are commercially available. In these assays, cells seeded at high density will establish polarity that can be assessed by determining the localization of proteins expressed on either the apical or basolateral membranes using fluorescence microscopy. The integrity of the cell monolayer is a critical factor for proper interpretation of these assays. To assess this, measurements of transepithelial electrical resistance (TER) and/or paracellular diffusion of a tracer molecule of known molecular mass, such as radiolabeled inulin, are routinely used to reflect tight junction integrity prior to and during viral infection.

The characteristics of cell lines used most often in Transwell assays (*e.g.*, cell-specific TER) have been well established (**Oztan et al., 2008**). Culture conditions in the two chambers can be modified to recapitulate *in vivo* properties, for example differences in pH between apical and basolateral fluids. Assays can also be modified to determine how different populations of cells impact transcytosis, by co-culturing different cell types, and to answer specific questions such as directionality of infection, infectivity of transcytosed virus, and contact-dependent transcytosis. Thus, in addition to documenting the absence of excessive paracellular diffusion, a proper viral transcytosis assay will assess (1) viral uptake from one side of the monolayer, (2) its appearance on the opposite side, (3) any intracellular accumulation of virus-derived material, and (4) any possible modification or degradation of viral material during the overall transcytosis process.

Several cell lines have been extensively used for these polarized cell culture models. These include Madin-Darby canine kidney (MDCK) cells (**Oztan et al., 2008**), which are easily cultured and establish polarity in less than a week, are readily infected by many types of viruses, and can be modified genetically. These cells can also be engineered to stably express the polymeric immunoglobulin receptor (pIgR), and thus can be used to study the role of IgA-dependent transcytosis during viral infections as discussed below. However, MDCK cells almost never represent the natural target cell for the virus in question. Viral transcytosis across intestinal epithelial cells has commonly been studied using Caco-2 cells, which differentiate along a crypt-to-villus axis and are easy to transfect. Efforts have also been made to model transcytosis of hepatitis viruses in hepatocytes using HepG2-N6 cells that express many liver-specific genes and can establish simple polarity in Transwell assays (**Snooks et al., 2008**). However, recapitulating the natural polarity of hepatocytes is difficult to accomplish in cell culture. The use of collagen gels employed in a sandwich configuration (*e.g.*, Matrigel) has improved efforts to establish polarization of primary hepatocyte cultures. 'Organoids' derived from animal or human tissue provide novel opportunities for achieving polarized cell function *in vitro* and are likely to open up new avenues in the future for studying directional viral entry, transcytosis, and release.

Fig. 3 Common pathways of endocytosis involved in transcytosis of viruses. Viruses can be internalized through different mechanisms of endocytosis. Macropinocytosis is an actin-dependent process regulated by Ras and PI3K in which molecules and fluid are engulfed from the extracellular space into a macropinosome. Receptor-mediated endocytosis involves the recognition of a ligand, such as a viral protein or immunoglobulin, through specific binding events and the subsequent formation of a clathrin-coated pit that internalizes the ligand in the form of a basket. Dynamin facilitates the scission of the pit off the plasma membrane, resulting in a clathrin-coated vesicle that will eventually uncoat. Caveolae-dependent endocytosis occurs at specific areas of the plasma membrane known as lipid rafts. Caveolin proteins and specific lipids are the main regulators of caveolae formation. In all cases, these vesicles typically deliver their contents to endosomes that will transport the cargo across the cell.

Endocytic Mechanisms Leading to Transcytosis

Endocytosis is a critical step in the internalization of viruses destined for transcytosis, and three distinct mechanisms of endocytosis are known to be involved. These different mechanisms share several common features, including the binding of the virion to attachment factors and/or receptors on the plasma membrane, invagination of the local plasma membrane, followed by membrane scission and internalization of a free vesicle primed for transport with its cargo (Elkin *et al.*, 2016) (Fig. 3). Endocytosis remains an active field of investigation, however, and other mechanisms may come to light in the future (Hemalatha and Mayor, 2019).

Caveolin-Dependent Endocytosis

Caveolin-dependent endocytosis entails internalization of extracellular material through flask-shaped pits of 50–80 nm in diameter known as caveolae that are present on apical and basal membranes of endothelial cells (Parton, 2018). Biochemically, caveolae are characterized by the presence of caveolin-1 (CAV-1), an integral transmembrane cholesterol-binding protein, and an enrichment in specific lipids such as cholesterol, sphingolipids, and phosphatidylinositol (4,5)-bisphosphate [PIP₂], all of which are required for the formation and/or stability of caveolae. CAV-1 binding to cholesterol promotes its oligomerization and the subsequent formation of caveolae, and thus chemicals that bind to or deplete cholesterol from membranes such as filipin and methyl- β -cyclodextrin, respectively, inhibit caveolae function. Studies using simian virus 40 (SV40) were among the first to reveal that the entrapment of virions in pre-existing caveolae triggers local tyrosine kinase-dependent signaling events, transient depolymerization of the cortical actin skeleton, and recruitment of dynamin to facilitate the fission of virion-loaded caveolae vesicles (known as caveosomes) into the cytoplasm for subsequent sorting (Pelkmans *et al.*, 2002). Epstein-Barr virus (EBV) utilizes caveolae to initiate transcytosis and

translocate from the basolateral to apical (mucosal) membrane of oral epithelial cells (Tugizov *et al.*, 2013). The apical release of EBV virions results in their secretion into saliva, which is likely important for the oral transmission of this herpesvirus.

Macropinocytosis

EBV also undergoes transcytosis in the reverse direction, from apical to basolateral membranes. In the early stages of infection, this may facilitate the transport of virus to B lymphocytes lying beneath the tonsillar epithelium which are permissive for productive infection. Apical-to-basolateral transcytosis of EBV is relatively rapid, and complete within 4 h, prior to the appearance of any progeny virions. It is not dependent on caveolae, but mediated instead by macropinocytosis, a distinct mechanism of endocytosis involving the non-selective ingestion of extracellular solutes and fluids by cells (Tugizov *et al.*, 2013). Macropinocytosis is characterized by the formation of a hollow ring of actin polymerization under the plasma membrane forming a circular ruffle. The closure of this ruffle and dissociation of actin filaments, steps regulated by the Ras protein and accumulation of phosphatidylinositol (3,4,5)-trisphosphate (PIP₃), leads to the formation of a relatively large 'macropinosome' vesicle (0.2–5 µm in diameter) primed for intracellular trafficking (Bloomfield and Kay, 2016). In addition to mediating apical-to-basolateral transcytosis of EBV, macropinocytosis has been implicated in the cellular entry of several other herpesviruses. Thus, endocytic mechanisms resulting in viral entry and productive infection overlap those associated with transcytosis. Why EBV uses two distinct endocytic mechanisms to initiate transcytosis in different directions (caveolae for basolateral-to-apical transcytosis, and micropinocytosis for the reverse) remains to be determined, but differences in plasma membrane protein and lipid composition may be at least partially responsible. In contrast to EBV, caveolae appear to mediate the apical-to-basolateral transcytosis of some adeno-associated viruses (AAV) (Di Pasquale and Chiorini, 2006), highlighting the complexity of the process and the diversity of signals that are likely involved in regulating transcytosis. This diversity is further highlighted by the fact that mice that are genetically incapable of forming caveolae are able to support transcytosis (Drab *et al.*, 2001).

Receptor-Mediated, Clathrin-Dependent Endocytosis

In addition to being nearly ubiquitous among different cell types, caveolae and macropinocytosis both share an independence from the requirement for a specific cellular receptor to trigger their activity. As such, these endocytic pathways are commonly referred to as receptor-independent. While both are undoubtedly involved in viral transcytosis, a third, clathrin-dependent endocytosis has been the most extensively documented and characterized (McMahon and Boucrot, 2011). This process involves the recognition of extracellular ligands – including viral proteins and immunoglobulin (Ig) receptors – by transmembrane receptors and the subsequent recruitment of clathrin and adapter proteins (APs) to the cytoplasmic face of the plasma membrane for the formation of vesicles. As such, this mechanism of entry provides higher specificity than receptor-independent endocytosis. Adapter complexes, such as that involving adapter protein 2 (AP2), recognize signals in the cytoplasmic tails of plasma membrane-anchored receptors and recruit clathrin molecules to initiate the polymerization and growth of a lattice that eventually coats the invaginating vesicle in the form of a basket known as clathrin-coated pit (McMahon and Boucrot, 2011). As for caveolae and some specific cases of macropinocytosis, dynamin is required for abscission of the membrane of the clathrin-coated vesicle from the plasma membrane. While clathrin-dependent endocytosis is directly involved in the canonical entry pathways of many diverse viruses, its role in viral transcytosis is almost exclusively linked to usage of Ig and Ig receptors as shuttles.

Immunoglobulins as Mediators of Transcytosis

Transcytosis plays an important role in the production of secretory immunoglobulins A and M (SIgA and SIgM) that provide protection against viruses at mucosal barriers (Turula and Wobus, 2018). These polymeric immunoglobulins (pIg) are produced by plasma cells within the lamina propria underlying the epithelial cell barrier. They undergo basolateral-to-apical transcytosis across this barrier upon binding the polymeric immunoglobulin receptor (pIgR). pIgR-pIg complexes are internalized by clathrin-mediated endocytosis, followed by vesicle-mediated transport from early endosomes near the basolateral membrane of the epithelial cell to Rab17-positive recycling endosomes at the apical membrane. Proteolytic cleavage of pIgR at its transmembrane domain results in release of the secretory component of pIgR bound to pIg as SIgA or SIgM into the lumen of the gut or bronchus. These secretory pIg complexes protect the epithelial surface but can also neutralize virus within endosomal compartments (Mazanec *et al.*, 1992). SIgA has been shown to mediate protection against many viruses, including Sendai virus, influenza A virus, measles virus, human immunodeficiency virus (HIV), reovirus and rotavirus (Turula and Wobus, 2018). Some viruses, such as simian immunodeficiency virus (SIV), downregulate pIgR expression in mucosal cells to impede Ig-mediated neutralization.

Although virus-specific immunoglobulins are typically protective against viruses at mucosal surfaces, in some cases antibodies promote dissemination of the virus within the host by facilitating transcytosis. The binding of virus-specific secretory IgA to EBV promotes internalization of the virus in epithelial cells expressing the pIgR, and this has been shown to allow the virus to enter and initiate replication within cells that are otherwise refractory to direct infection (Sixbey and Yao, 1992). Acting similarly,

EBV-specific immunoglobulins have been shown to mediate basolateral-to-apical transcytosis of EBV across polarized cultures of MDCK cells (Gan *et al.*, 1997), and may promote the apical-to-basolateral transcytosis of EBV across the tonsillar epithelium by micropinocytosis, as discussed above (Tugizov *et al.*, 2013). IgA-mediated transcytosis has also been described for human cytomegalovirus (HCMV), HAV and other viruses, as discussed in greater detail below.

Endocytic Sorting and Vectorial Transport of Vesicles

Endocytic vesicles can have one of several fates, including recycling back to the original plasma membrane, delivery of cargo to the lysosome for degradation, or transcytotic shuttling (Elkin *et al.*, 2016). This decision is controlled by a myriad of cellular proteins and lipids that must act in concert to ensure proper delivery of cargo and that are only partly understood. A detailed discussion of vesicle trafficking in polarized epithelial cells is well beyond the scope of this review. However, important regulators of trafficking can be grouped generally into three categories: the SNARE (Soluble NSF [N-ethylmaleimide-sensitive factor] Attachment Protein Receptor) proteins, Munc-18/Sec1 proteins, and Rab proteins.

SNARE proteins constitute a family of membrane-associated proteins present on vesicles (*v*-SNAREs) or target vesicles (*t*-SNAREs) that are involved in promoting membrane docking and fusion through interactions with NSF and its attachment factor, alpha-soluble NSF attachment protein (α -SNAP) (Wang *et al.*, 2017; Han *et al.*, 2017). In general, SNARE-dependent membrane targeting requires (1) SNARE activation and recruitment of specific Rab proteins to the proper membrane, (2) formation of cognate membrane attachment complexes provided by specific pairwise coupling of SNARE isoforms, and (3) membrane fusion and cargo mixing or release (Han *et al.*, 2017). The cytosolic NSF adapter protein is required for membrane fusion and is a critical regulator of polarized plasma membrane targeting, including IgA transcytosis (Apodaca *et al.*, 1996; Rothman, 1987). Following its discovery, the SNAP family of NSF receptors was shown to recruit NSF to specific organelles and to activate its ATPase activity. While SNARE proteins were initially thought to contribute to the specificity required for vesicle and target membrane fusion, the localization of specific SNAREs – 38 of which are known to date – to specific organelles and plasma membrane domains appears to be cell type-specific. Nonetheless, these proteins all function during tethering of a vesicle (*e.g.*, secretory vesicle) to a target membrane (*e.g.*, plasma membrane) and assist with the biophysical and energetic requirements for membrane fusion of the independent lipid bilayers. This is accomplished by interactions between three or four *v*- and *t*-SNAREs that result in the formation of a complex that bridges the membranes in the form of a molecular zipper and ultimately fuses the membranes. Thus, SNARE proteins and their adapters are critical for both the proper endocytic sorting and fusion of virion-loaded endosomes to secretory vesicles and the subsequent secretion of these vesicles upon fusion with the plasma membrane.

SNARE proteins function in concert with Munc-18/Sec1 that regulates vesicle docking and are associated with the plasma membrane through interactions with SNAREs. These proteins promote stability and spatially correct assembly of SNAREs complexes in vesicles, and may further assist in promoting SNARE-dependent membrane fusion (Wang *et al.*, 2017; Han *et al.*, 2017). The small GTP-binding Rab proteins constitute a third group of endocytic regulators involved in intracellular vesicle movement during transcytosis (Bhuin and Roy, 2014). At least 60 Rabs have been identified in mammalian cells and their expression – as with the SNAREs – is dependent on the cell type. Some of these proteins localize to specific domains of the plasma membrane in polarized cells, highlighting their function in transcytosis. For example, Rab11 and Rab25 regulate basolateral-to-apical transcytosis and inhibition of their function leads to accumulation of IgA in the apical recycling endosome and poor delivery to the apical plasma membrane. Rab proteins appear to facilitate vectorial trafficking of vesicles through associations with the cytoskeleton. As for Munc-18 proteins, Rabs are also involved in promoting vesicle docking and priming; and some Rabs may even recruit NSF and SNAREs to drive formation of the complex.

The cytoskeleton also plays a key role in the trafficking, and ultimately secretion, of endocytic vesicles involved in transcytosis (Apodaca, 2001). While microtubule function is not directly required for transcytosis, it does provide a molecular highway for vesicles to travel from one side of the cell to the other and is essential for the maintenance of cell polarity. RhoA, Rac1 and other Rho GTPases functionally integrate the organization of the cytoskeleton for membrane trafficking (Aspenström, 2014). Specific lipids with signaling properties – such as phosphoinositides, cholesterol, and glycosphingolipids – contribute as well. Reductions in phosphoinositide 3-phosphate (PI3P) resulting from pharmacological inhibition of phosphoinositide 3-kinase (PI3K) by inhibitors such as wortmannin and LY294002 have well known detrimental effects on endocytic trafficking. Inhibition of PI3K impairs basolateral-to-apical transcytosis of dimeric IgA and pIgR (Vergés *et al.*, 2007).

Secretion of Cargo

The final step in transcytosis involves the tethering of the secretory vesicle to the plasma membrane, SNARE-mediated fusion of the two membranes, and secretion of cargo. In eukaryotes, the exocyst complex is responsible for the initial tethering interaction between the secretory vesicle and the plasma membrane (Martin-Urdiroz *et al.*, 2016). Exocyst function is aided by Munc-18/Sec1 and is believed to bridge the SNAREs on the secretory vesicle and the plasma membrane. This evolutionarily conserved octameric complex – composed of Sec3, Sec5, Sec6, Sec8, Sec10, Sec15, Exo70, and Exo84 – localizes to the cytoplasm, the trans-Golgi network, recycling endosomes, and specific domains of the plasma membrane. In the current model, Exo70 recruits other components of the exocyst to apical or basolateral membranes through interactions with specific lipids in the inner leaflet. This interaction is critical for assembly of the exocyst complex at the plasma membrane and for the docking and fusion of secretory vesicles (He and Guo, 2009).

Fig. 4 Transcytosis contributes to viral pathogenesis in diverse tissues. (A) Viral transcytosis and retrotranscytosis across the gastrointestinal tract. (B) Hepatocyte polarity and basolateral-to-apical transcytosis resulting in virus release into the biliary tract. LSEC = liver sinusoidal endothelial cell. (C) Structure of the blood-brain barrier and apical-to-basolateral transcytosis of Virus Researchulting in neuroinvasion. (D) Structure of a placental villous tree and apical-to-basolateral transcytosis of viruses from the maternal blood to fetal tissue.

Transcytosis and Viral Pathogenesis

Cell polarity is essential for the three-dimensional development of tissues and the creation of protective barriers between cells and the external environment. Transcytosis itself contributes to cell polarity through directional transport of *de novo* synthesized proteins to specific domains of the plasma membrane (Garcia-Castillo *et al.*, 2017). Polarized cells possess distinct populations of endocytic vesicles, such as 'apical' and 'basolateral' endosomes, depending on their location and biochemical composition. Although transcytosis is defined as the directional movement of cargo within polarized cells, several cell types that lack clear apical-basal polarity, such as neurons and osteoclasts, employ similar strategies to transfer macromolecules between distinct extracellular environments (Coxon and Taylor, 2008). Transcytosis allows for directional viral entry and secretion from apical and/or basolateral membranes and is a critical factor in the pathogenesis of many viral infections. This section presents some additional examples of viruses that use transcytosis to cross cellular barriers in diverse organs and discusses the cell types involved in this process.

Breaching Epithelial Barriers

Enteric viral infections constitute a major burden in public health and several related viruses have been demonstrated to use transcytosis to facilitate dissemination within the gastrointestinal tract. Human noroviruses (HuNoVs) are responsible for a large number of gastroenteritis outbreaks around the world and are a leading cause of severe childhood diarrhea in the United States. While the precise mechanisms by which HuNoVs infect the intestinal tract and induce pathology remain debated, both HuNoVs and murine noroviruses (MuNoVs) undergo transcytosis across intestinal epithelial cells *in vitro* in the absence of productive infection (Karst and Wobus, 2015). Noroviruses are transcytosed from the gut lumen to the lamina propria through M-like cells where they may infect immune cells resident within Peyer's patches (Fig. 4(A)). Recent studies using jejunal enteroids show that HuNoVs also replicate in enterocytes, which may be more important target cells in the pathogenesis of the infection (Ettayebi *et al.*, 2016).

Secretory immunoglobulin-virus complexes in the lumen of the gut can be sampled and endocytosed by specialized microfold cells (M cells) overlying mucosal-associated lymphoid tissue by a process known as 'retrotranscytosis' (Fig. 4(A)). The apical-to-basolateral retrograde transport of SIg complexes and other antigens to immune cells residing beneath the epithelium in Peyer's patches within the lamina propria is important for normal immune responses and the maintenance of tissue homeostasis (Kobayashi *et al.*, 2019). M cells may serve as portals for viral entry and dissemination, as transcytosis of virus across M cells may allow subsequent infection of epithelial cells from their basolateral surface, or invasion of cells residing within the lamina propria. Although it is not clear that transcytosis is required for infection of enterocytes, MuNoV titers were reduced in mice in which M cells were depleted (Gonzalez-Hernandez *et al.*, 2014). Poliovirus undergoes transcytosis in Transwell experiments utilizing Caco-2 human intestinal epithelial cells, and apical-to-basolateral transcytosis across M cells may allow it to breach the gastrointestinal epithelial barrier (Ouzilou *et al.*, 2002). Support for this hypothesis comes from electron microscopy studies that have documented the presence of poliovirus virions within villous M-like cells in tissue from humans and experimentally-challenged rhesus monkeys (Takahashi *et al.*, 2008; Siciński *et al.*, 1990). The mechanistic details of transcytosis are uncertain, including which endocytic pathway is utilized and whether a specific cellular receptor is required.

A particularly interesting example of viral transcytosis is provided by HIV. Upon contacting the apical surface of an epithelial cell, HIV-infected peripheral blood leukocytes have been shown to release virus in a vectorial fashion towards the epithelial surface (Bomsel, 1997). The released virus undergoes rapid transcytosis, emerging on the basolateral side of the epithelial barrier within 30 min where it can then infect macrophages and lymphocytes resident within the submucosa.

Neuroinvasion

The blood-brain barrier (BBB) shields the brain both physically and metabolically, and acts as a highly selective portal for nutrient delivery to the brain. It is comprised primarily of brain microvascular endothelial cells (BMECs), supported by a network of underlying astrocytes and pericytes embedded in the basement membrane surrounding the vasculature (Hou *et al.*, 2016; Engelhardt and Sorokin, 2009). The BBB is essential for maintenance of homeostasis within the brain microenvironment. It is oriented with its apical surface facing the systemic circulation, and the basolateral surface facing the abluminal (brain) side of the capillary endothelium. Barrier function is provided by tight junctions composed of transmembrane proteins including occludin, claudins, and junctional adhesion molecules. Positioned between adjacent cells, the tight junctions limit free fluid exchange and paracellular diffusion of solutes (Fig. 4(B)). Transcytosis across BMECs is highly restricted and actively regulated. Both caveolae- and clathrin-mediated endocytosis occur in BMECs, with caveolae-dependent endocytosis more prevalent (Ayloo and Gu, 2019). Micropinocytosis is less evident.

Despite the strong physical barrier provided by the BBB, a lengthy list of viruses is capable of breaching it and invading the central nervous system. Neuroinvasion can be achieved by multiple mechanisms, including non-hematogenous entry through peripheral nerves, but transcytosis across the BBB likely contributes to pathogenesis of some infections. Fluorescently-labeled Zika virus, a mosquito-borne flavivirus with severe consequences for the developing brain, has been shown to undergo energy-dependent transcytosis across polarized Transwell cultures of choriocarcinoma cells with impermeable tight junctions (Chiu *et al.*, 2020). Transcytosis was reduced by small molecule inhibitors of both clathrin-dependent and caveolae-mediated endocytosis. However, Zika virus has also been shown to productively infect BMEC, and to be released on the basolateral side of an impermeable model BBB without destroying its integrity (Mladinich *et al.*, 2017). Thus, the importance of transcytosis in neuroinvasion by Zika virus remains uncertain. More convincing evidence exists for encephalitic alphaviruses. Electron microscopy demonstrated the presence of immunogold-labeled Venezuelan equine encephalitis virus (VEEV) particles within cortical BMECs of infected mice, and VEEV was shown to undergo caveolae-mediated apical-to-basolateral transcytosis in Transwell cultures of primary murine BMECs (Salimi *et al.*, 2020). Transcytosis was inhibited by both interferon and small molecule inhibitors of RhoA GTPases. Consistent with these *in vitro* observations, VEEV titers were reduced in the brains of CAV-1 knockout mice without reductions in the titer in other organs (Salimi *et al.*, 2020). These latter findings provide strong support for caveolae-mediated transcytosis across the BBB playing an important role in neuroinvasion by alphaviruses.

AAV has been considered as a possible vector for gene therapy in the central nervous system, resulting in considerable interest in its potential for transcytosis across the BBB. AAV9 has been shown to be transported across polarized monolayer cultures of primary human BMECs without increases in paracellular diffusion, with release occurring on the basolateral side of the monolayer within 3 h (Merkel *et al.*, 2017). AAV9 transcytosis was notably more efficient than AAV2 transcytosis, and also possessed greater gene transduction activity within the central nervous system. By contrast, AAV2 demonstrated greater transduction activity within the BMEC monolayer. Differences in AAV9 and AAV2 may reflect utilization of different cell attachment factors, with AAV2 binding to heparan sulfate proteoglycans and AAV9 suggested to bind galactose moieties on the apical BMEC membrane (Merkel *et al.*, 2017).

Viral Hepatitis

The liver is the largest metabolic organ in the human body and responsible for synthesis of bile acids, lipoproteins, clotting factors and other multiple plasma proteins. It has a unique vascular circuit in which venous blood coming from the intestines *via* the portal vein and arterial blood from the hepatic artery pass through sinusoids aligned along linear arrays of hepatocytes, the major cell type in the liver (Fig. 4(C)). The hepatocytes are separated from the sinusoids by rows of liver sinusoidal endothelial cells

(LSECS) with fenestrae that provide access from the sinusoids into the space of Disse that exists between LSECS and hepatocytes (Shetty *et al.*, 2018). Hepatocytes are of epithelial origin and are highly polarized, with their basolateral surface facing onto the space of Disse, and with tight junctions on their lateral surfaces bracketing a much smaller apical membrane surface that opens into small canals (biliary canaliculi) that drain bile into the biliary tract (Gissen and Arias, 2015). The apical and basolateral membranes of hepatocytes are thus separated by the tight junctions that seal the canalicular lumen. The apical membrane is metabolically highly active and responsible for the secretion of bile salts that are ultimately delivered to the gastrointestinal tract (Fig. 4(C)). Given this organization, viruses typically reach hepatocytes hematogenously, through sinusoidal blood, and enter hepatocytes through the basolateral membrane.

Productive infection of hepatocytes results in either the basolateral release of viral particles back to the sinusoidal blood for spread within the liver, apical release of virus into the biliary tract for eventual shedding in feces, or a combination of both. Five very different viruses have primary tropism for the hepatocyte, only two of which retain significant infectivity in the bile: HAV (a picornavirus) and HEV (a hepevirus). Hepatitis B virus (HBV, an hepadnavirus), hepatitis C virus (HCV, a flavivirus), and the satellite-like hepatitis D virus, each possess lipid envelopes that are essential for their infectivity and that are destroyed by the high concentrations of unbuffered bile salts present in the proximal biliary canaliculus. Transcytosis can thus contribute only to the pathogenesis of HAV or HEV infection in hepatocytes, and only in a basolateral-to-apical (sinusoids to biliary canaliculus) direction.

Although distantly related phylogenetically, HAV and HEV share an unusual lifecycle in which they are shed from infected persons in feces as naked virus particles lacking envelopes, but circulate within the blood during acute infection cloaked in host membranes (Feng *et al.*, 2014). In the case of HAV, these ‘quasi-enveloped virions’ (eHAV) are small membranous vesicles resembling exosomes that contain one or more capsids (Feng *et al.*, 2013). eHAV vesicles are as infectious as the naked virus (nHAV), and enter cells through a complex endocytic pathway in which the membranes surrounding the capsid are degraded in late endolysosomes (Rivera-Serrano *et al.*, 2019; Das *et al.*, 2020). Quasi-enveloped virions are the dominant (perhaps only) form of these viruses released from cells, and both eHAV and eHEV are released from the basolateral membrane as well as the apical membrane of infected hepatocytes (Capelli *et al.*, 2019; Hirai-Yuki *et al.*, 2016). This results in their secretion into both blood and bile. Bile salts strip the membranes from virus released into the biliary canaliculus, explaining why only naked virions are shed in feces. This unusual lifecycle allows for stealthy spread of virus within the host, in a membrane-cloaked form sequestered from the immune system, coupled with efficient transmission of stable, non-enveloped particles to naïve hosts through the environment. Transcytosis across polarized, nonpermeable cell monolayers occurs only at very low rates for both HAV and HEV in Transwell assays (Capelli *et al.*, 2019; Blank *et al.*, 2000). However, transcytosis of antibody-virus complexes has been suggested to contribute to the pathogenesis of hepatitis A in humans.

Studies by Dotzauer *et al.* (2000) demonstrated that HAV can gain entry into otherwise poorly permissive mouse hepatocytes when complexed with virus-specific IgA. Endocytosis of the IgA-virus complex may have been driven in part in these studies by binding to the asialoglycoprotein receptor (ASGPR) expressed by hepatocytes. However, the pIgR was subsequently shown to mediate apical-to-basolateral transcytosis of IgA-coated HAV particles across polarized epithelial cells (Dotzauer *et al.*, 2005). Elegant experiments done much later in mice revealed that intravenously administered HAV undergoes transcytosis across the liver, from the circulation to the biliary tract and thence to feces (Counihan and Anderson, 2016). Transcytosis occurred at a low basal rate in mice, but was increased to ~9% over a 4 h period when virus was bound to a poorly neutralizing IgA antibody. Viral uptake into hepatocytes was dependent upon the murine pIgR, as transcytosis was not observed in mice in which this gene was knocked out (Counihan and Anderson, 2016). Transcytosis and fecal shedding were also not observed when virus was complexed with a potent neutralizing IgA antibody. Despite their elegance, the relevance of these observations to fecal shedding of HAV during acute hepatitis A is doubtful, as virus circulating in the blood and passing through the hepatic sinusoids is mostly if not entirely quasi-enveloped and incapable of binding HAV-specific antibodies (Feng *et al.*, 2013). Moreover, most fecal shedding of virus occurs prior to the development of humoral immunity to the virus, and the transcytosis rate observed in the absence of antibody cannot account for the large amounts of virus shed in feces (Counihan and Anderson, 2016; Lanford *et al.*, 2011). On the other hand, transcytosis of naked HAV virions across the gastrointestinal mucosa, perhaps in M cells, provides an attractive explanation for how virus might initially reach the liver in the absence of productive replication within the gut, which has never been demonstrated.

Fetal Infections

The placenta provides the growing fetus with physical and immunological protection against blood-borne pathogens during pregnancy, while also ensuring delivery of essential nutrients and oxygen. The main cell type in the placenta, a specialized epithelial cell known as the trophoblast, exists in two distinct layers (Fig. 4(D)): an inner layer composed of mononucleated cytotrophoblasts positioned at the fetal interface that retain proliferative activity and serve as progenitor cells, and an outer layer consisting of a syncytium of terminally-differentiated syncytiotrophoblasts facing onto the maternal circulation (Turco and Moffett, 2019). The latter are highly polarized and characterized by a dense layer of microvilli with expression of the neonatal IgG receptor (FcRn) on the apical membrane facilitating apical-to-basolateral transport of maternal IgG to the fetus by transcytosis (Pyzik *et al.*, 2019).

Several viruses that can be transmitted from the mother to the fetus *in utero* have been suggested to breach this barrier by undergoing apical-to-basolateral transcytosis across the syncytiotrophoblast epithelium. These include HIV and other lentiviruses, HBV, human cytomegalovirus (HCMV), and Zika virus (Lagaye *et al.*, 2001; Bhat and Anderson, 2007; Maidji *et al.*, 2006). With HIV,

close cellular contact between infected macrophages and the syncytiotrophoblast may be important for the initiation of transcytosis. In other cases, transcytosis may be receptor-dependent and involve virus-antibody complexes. For example, transcytosis of HCMV appears to be mediated by the interaction of immunoglobulin-coated virions with FcN expressed by syncytiotrophoblasts in placentas from women with low levels of neutralizing antibodies to the virus (Maidji *et al.*, 2006). Studying the transcytosis of viruses across the placental barrier has been historically challenging due to limitations of *in vitro* models that fail to accurately recapitulate the structure of the human placenta. Moreover, it may be difficult to discriminate between transcytosis and other mechanisms that may lead to breaching of the placental barrier, such as the productive infection of trophoblasts by Zika virus (Aagaard *et al.*, 2017). Decreased tight junction function leading to increased paracellular permeability of the syncytiotrophoblast layer also has been observed in Zika virus-infected women (Miranda *et al.*, 2019). The recent development of trophoblast organoids is likely to provide new opportunities to determine how viruses cross the barrier provided by the placenta.

Extracellular Vesicle-mediated Export of Viruses

Nonlytic Release of Virus in Extracellular Vesicles

Many viruses that have been classified canonically as ‘nonenveloped’ are released nonlytically from infected cells in extracellular vesicles (EVs), a phenomenon that has potentially strong consequences for the course of infection and the host immune response to it (Feng *et al.*, 2013; Robinson *et al.*, 2014; Santiana *et al.*, 2018; van der Grein *et al.*, 2019). As discussed above, both HAV and HEV, positive-strand RNA viruses that infect the liver, are released from the basolateral surface of hepatocytes into the bloodstream where they circulate cloaked in lipid membranes that protect the capsid from neutralizing antibodies (Feng *et al.*, 2013; Feng *et al.*, 2014). Quasi-enveloped eHAV virions possess a specific infectivity similar to naked HAV virions, are ~50–110 nm in diameter, and have a buoyant density of ~1.100 gm/cm³ in iodixanol gradients. eHAV enters cells to initiate infection *via* clathrin-dependent endocytosis, enabled in part by receptors such as TIM1 on the cell surface that recognize phosphatidylserine displayed on the exterior of eHAV (Feng *et al.*, 2015; Das *et al.*, 2017; Rivera-Serrano *et al.*, 2019). The membrane is degraded by enzymes and cholesterol transporters in the late endolysosome, allowing the exposed capsid to bind gangliosides in the endolysosomal membrane that mediate later steps in entry resulting in release of the genome into the cytoplasm to initiate translation (Rivera-Serrano *et al.*, 2019; Das *et al.*, 2020).

Several other picornaviruses have been shown to be released from cultured cells in EVs, including coxsackievirus B3, poliovirus, and encephalomyocarditis virus (Robinson *et al.*, 2014; Chen *et al.*, 2015; van der Grein *et al.*, 2019; Yang *et al.*, 2020). These EVs are larger than eHAV vesicles, and contain large numbers of capsids. Infection with vesicles containing multiple viral capsids may result in the simultaneous introduction of multiple viral genomes into a newly infected cell. This ‘*en bloc*’ transmission of virus effectively raises the infection multiplicity and may provide some fitness advantages to the virus (Santiana *et al.*, 2018; Aguilera and Pfeiffer, 2019). Vesicle-mediated export has also been demonstrated for norovirus and rotavirus, and infectious vesicles containing rotaviruses and norovirus have been observed in fecal samples (Santiana *et al.*, 2018).

The release of virus in EVs involves membrane budding that is topologically the inverse of endocytosis (Fig. 1, right). Whereas vesicles resulting from endocytosis exclude cytoplasm and contain extracellular fluid, EV release results from budding in an outward direction from the cytoplasm with the resulting vesicle containing cytoplasmic contents. This difference in topology mandates the use of different cellular machinery to seal the membrane during abscission of the vesicle, with EV release being dependent upon endosomal sorting complexes required for transport, otherwise known as ESCRT (Vietri *et al.*, 2020), rather than the membrane remodeling activity of dynamin used in endocytosis. This outward budding of cytoplasmic contents can occur at the plasma membrane, resulting in the release of large ‘microvesicles’ from cells. However, such budding also occurs on endosomal membranes, resulting in intraluminal vesicles (ILVs) carrying cytoplasmic cargo, and ultimately large multivesicular endosomes (MVEs, sometimes called multivesicular bodies) containing multiple ILVs (Gruenberg, 2020). MVEs can fuse with lysosomes leading to degradation of their cargo, or traffic to the cell surface where fusion with the plasma membrane results in the release of ILVs to the external environment as ‘exosomes’, small vesicles capable of shuttling proteins and microRNAs between different cells (Colombo *et al.*, 2014).

Exosome-Like Release of Quasi-enveloped Viruses

In many ways, including their size and protein composition, eHAV vesicles resemble exosomes (McKnight *et al.*, 2017; They *et al.*, 2018). Both eHAV and eHEV appear to originate within MVEs and their release is highly dependent upon ESCRT and conserved protein motifs (‘late domains’) present in the structural proteins that mediate interactions with ALIX and TSG101, ESCRT-associated proteins. These late domains are similar to those present in structural proteins of canonical enveloped viruses (PPXY, P(S/T)AP, GPPX₃Y, or YPX₁₀₃L) that mediate interactions with ESCRT machinery (Chen and Lamb, 2008; Ren and Hurley, 2011). Quasi-envelopment of these hepatitis viruses thus shares several features in common with the budding of canonical enveloped viruses, which is considered elsewhere in detail in this volume. A major difference, however, at least with eHAV, is that virus assembly (assembly of the capsid and encapsidation of the genome) occurs prior to and independent of recruitment of the virus as cargo to be loaded into ILVs (Fig. 1, right). By contrast, assembly of canonical enveloped viruses typically occurs at the membrane and is coupled to budding.

ESCRT complexes play a key role in eHAV and eHEV release. Three distinct ESCRT protein complexes act sequentially to sort and load cargo into MVBs (Hurley, 2015; Votteler and Sundquist, 2013; Votteler *et al.*, 2016). ESCRT-I and ESCRT-II are core ESCRT machinery that sort cargo and sequester it at the endosomal membrane, creating an inward bud (Hurley, 2015). ESCRT-III oligomers are subsequently recruited and form a complex that pinches the neck of the membrane invagination, releasing the bud into the endosomal lumen and sealing the membrane, thus forming an ILV. In a later step, the ATPase VPS4 acts to dissociate the ESCRT-III oligomers. As indicated above, two ESCRT-associated proteins are important for the release of eHAV or eHEV in vesicles: TSG101 and ALIX. TSG101 is associated with ESCRT-I, whereas ALIX is an accessory ESCRT protein that feeds into ESCRT-III complexes in parallel with ESCRT-I/II. Interactions with it represent a second pathway for cargo selection. The HAV capsid interacts with ALIX through tandem YPX₃L late domain motifs in VP2 as well as in the C-terminal pX domain of the VP1pX protein, both of which contribute to eHAV release (Gonzalez-Lopez *et al.*, 2018; Jiang *et al.*, 2020). The HEV capsid interacts with TSG101 through a PSAP 'late domain' motif in its ORF3 protein which is similarly essential for release of quasi-enveloped virus (Nagashima *et al.*, 2011). siRNA knockdown of ALIX, CHMP2A (part of the ESCRT-III complex) or VPS4B strongly inhibit eHAV release, and both ALIX and VPS4 are physically present in extracellular eHAV vesicles (Feng *et al.*, 2013; McKnight *et al.*, 2017). Following formation of MVEs containing intraluminal eHAV or eHEV, the cues that result in their trafficking to the plasma membrane, where fusion results in release of quasi-enveloped virus to the extracellular milieu, are unknown.

Autophagy-Related Vesicle-Mediated Release of Virus

Autophagy is a complex and tightly regulated cellular process whereby unwanted cytoplasmic content becomes engulfed within double-membrane vesicles (autophagosomes) that fuse with lysosomes for degradation of their cargo (Levine and Kroemer, 2008). In some cases, however, autophagy does not result in lysosomal degradation but rather noncanonical secretion of cytoplasmic cargo isolated by the autophagic machinery (Ponpuak *et al.*, 2015). Secretory autophagy involves the movement of the autophagosome to the cell surface and fusion of its outer membrane with the plasma membrane. The membrane topology of autophagy has long been recognized to offer the potential for nonlytic release of viruses that assemble within the cytoplasm of infected cells (Jackson *et al.*, 2005). The topology is essentially the same as that described above for exosome-like release of quasi-enveloped viruses (Fig. 1, right). Autophagy is similarly ESCRT dependent (Vietri *et al.*, 2020; Zhou *et al.*, 2019).

While incompletely understood, it is becoming increasingly clear that multiple RNA viruses with cytoplasmic replication cycles subvert different facets of autophagy to promote both amplification of their genomes as well as their nonlytic release from cells in EVs. Viral particles assembling within the cytoplasm become engulfed in autophagosomes and subsequently undergo non-canonical secretion from the cell. Autophagic signaling is required for both the replication of poliovirus and other enteroviruses as well as their release from cells in EVs (Robinson *et al.*, 2014; Bird *et al.*, 2014). Coxsackievirus B3 is released in EVs associated with the autophagy-related protein, LC3. Poliovirus utilizes LC3 as well as a second autophagy-related protein, ATG9, to promote its intracellular replication, possibly contributing to membrane rearrangements required for the assembly of replication organelles that mediate viral RNA synthesis (Abernathy *et al.*, 2019). Autophagic signaling is induced in a noncanonical fashion, independent of the ULK1 kinase complex normally engaged in induction of autophagy (Corona Velazquez *et al.*, 2018). The enterovirus EV-D68, which is likely responsible for recent outbreaks of acute flaccid paralysis in children, also activates autophagy, but it also suppresses later steps in autophagy resulting in decreased autophagic flux (Corona *et al.*, 2018). A protease expressed by the virus cleaves SNAP29, a SNARE protein engaged in regulating autophagosome-lysosome fusion, thereby redirecting autophagic trafficking and limiting degradative autophagic flux.

Glossary

Anthropogenic factors Refers to effects, processes, objects, or materials that are derived from human activities, as opposed to occurring in natural environments. They can include the effects of human trade, commerce, farming, land use, urbanisation, effects on wild animals and even climate change.

Arboviruses The term “Arboviruses” is an abbreviation of “arthropod borne viruses” and includes viruses that are transmitted between their host species by arthropod vectors.

Epizootic An epizootic is a disease occurrence in a nonhuman animal population that is analogous to an epidemic in humans. It may be restricted to a specific locale (an “outbreak”), can be general (an “epizootic”), or more widespread (“panzootic”).

Haematophagous arthropods These are arthropods that can mediate the transmission of infectious pathogens, and can include, ticks, mosquitoes, sand flies and *Culicoides* midges and biting flies.

Mechanical transmission This describes the simple physical movement of a virus from one infected host to

another susceptible host, usually by an arthropod vector, allowing infection to occur, without infection or replication in the vector.

Naïve A term used to describe animals or animal populations that have not previously come into contact with a pathogen and therefore have no acquired immunity to the disease agent.

Persistent infection Many arboviruses will infect their vectors and vector cells for life, often with little discernible effect on the individual vector. As a result, once infected the vector can usually transmit the virus throughout its life.

Vector capacity This capacity of an arthropod population reflects its ability to transmit the pathogen to the host population, within a specific ecosystem-setting and measures the efficiency of virus transmission between hosts.

Vector competence It is an assessment of the capability of a given vector to transmit a specific virus to its host.

Zoonosis An infection or disease that can be transmitted from animals to humans under natural conditions, also: an infection or disease that can be transmitted between animals and humans (bidirectional zoonosis).

Introduction

The term “Arboviruses” is an abbreviation of ‘arthropod borne viruses’ and includes viruses that are transmitted between their host species by arthropod vectors. For many years after the discovery of yellow fever virus (YFV) by Walter Reed in 1900, the confirmation of Carlos Finlay’s findings that YFV is transmitted by mosquitoes, and the discovery of the first African horsesickness virus by M’Fadyean in 1900, the arboviruses were considered to be a singular unique group. It was even supposed that arboviruses formed a natural taxonomic group.

The arboviruses include viruses that are mechanically transmitted, for example on the mouth parts of haematophagous arthropods, as well as viruses that are ingested, before passing through the arthropod vectors system, before being transmitted in its saliva during feeding on another host. However, in a strict sense, ‘true’ arboviruses are regarded as those agents that infect and replicate in both the host species and the arthropod vector.

In the 1960s and 1970s it became clear that the arboviruses fall into different taxonomic groups. In 1968–1971 the first biophysical, biochemical and morphological characterization of these viruses permitted their initial taxonomic classification. The development of better serological and/or molecular tools, including sequencing and genomics, is at the heart of the identification of different taxonomic groups of viruses and a rapid expansion of the number of identified virus species, genera, families and orders.

Arbovirus vectors include a wide range of arthropods. The first indication that an arthropod could transmit a pathogen to humans, came after the work of Sir Patrick Manson in 1878, when he identified mosquitoes to be the ‘nurse’ or vector of filarial worms.

WHO defines arboviruses as “viruses that share the characteristic of being naturally maintained through biological transmission between susceptible vertebrate hosts by haematophagous arthropods, or transovarial transmission from infected female arthropods to her progeny”. However, the arboviruses also include viruses that can specifically infect and replicate in their arthropod vectors and are then transmitted by them between individual susceptible plants or animals. The plant viruses can be transmitted by a range of vectors including nematodes, fungi and arthropods (aphids, leafhoppers, treehoppers, thrips, whiteflies, mealybugs,

beetles, mites), which can be either persistently or non-persistently infected. The biting-chewing herbivorous insects, like thrips, or beetles and piercing-sucking insects like aphids, are the most common vectors of the plant arboviruses.

This article focuses on the transmission of those arboviruses that infect animals, which includes those transmitted by haematophagous arthropods (ticks, mosquitoes, sandflies, biting midges and flies). Although certain animal arboviruses can be transmitted mechanically, the principal mode of transmission of the animal arboviruses, involves infection of individual vectors by virus ingested as part of a blood-meal from an infected host, followed by virus replication, and after an extrinsic incubation period, the ability to transmit the virus to other hosts (persistent transmission).

The "genomics era" has unravelled some of the complexity of the arboviruses, their evolutionary relationships and their close associations with specific groups of vectors. For example, links were revealed between the flaviviruses and a group of segmented "flavi-like" viruses identified in ticks or mosquitoes such as Jingmeng tick virus and Guaico *Culex* virus (with 4 ssRNA genome segments). Homology was detected particularly in the RNA-dependent RNA polymerase, with the genes of the non-segmented flaviviruses.

To date, at least 500 animal arboviruses have been identified, almost all of which are RNA viruses. However, African swine fever virus (ASFV) is a large dsDNA virus that can be transmitted by *Ornithodoros* ticks, although it can also be transmitted in the absence of ticks by other routes. The animal Arboviruses can be transmitted by ticks, mosquitoes, sandflies or *Culicoides* biting midges, approximately half by mosquitoes, a third by ticks and the rest by sandflies or biting midges. These arboviruses are often dependent on their ability to replicate in two very different species (their vectors and vertebrate hosts) both of which can act as an amplifier and/or reservoir, for their continued transmission and survival.

The arboviruses can have important impacts on human and animal health. They are either epizootic or zoonotic. Emergence and/or re-emergence of the arboviruses is a challenge that humanity will face during the current century. Incursions into novel geographical regions are becoming more frequent. For example, bluetongue disease of ruminants caused by bluetongue virus infection was considered for a long time as a tropical disease, based on its geographical distribution between approximately 40°N and 35°S. However, during the second half of the 20th century, it emerged all around the world, including for the first time in northern Europe, disrupting trade and causing severe economic damage.

Arthropod Vectors of Animal Arboviruses

Except for those arboviruses that can be transmitted mechanically, or by a direct animal to animal route, the animal arboviruses ingested in a contaminated blood meal must infect and further replicate within the arthropod-vector, in order to be transmitted during a later blood meal. Transmission of arboviruses by arthropod vectors can be influenced by a number of variables, which include the vectorial capacity/vector competence of the vector population /individual and the entomological inoculation rates. Vectorial capacity of an arthropod population reflects an ability to transmit the pathogen to the host population within a specific ecosystem-setting and measures the efficiency of a virus transmission between hosts. Vector competence is an assessment of the capability of a given vector to transmit a specific virus. Vectorial capacity is measured by the formula $C = ma^2VP^n / -\log_e P$, where C is the vectorial capacity (the number of infectious bites that the host is subjected to per day), m is the vectors' density relative to the host's density, a is number of vectors feeding on a host divided by the duration of the gonotrophic cycle (gonotrophic cycle: blood-feeding, egg maturation and oviposition) in days, V is the vector competence, P is the daily survival of vectors and n is the extrinsic incubation period. Another variable which helps estimating risk of transmission and disease is the entomological inoculation rate. Entomologic inoculation rate is calculated by multiplying the mosquito biting rate and relative number of infected mosquitoes in a population.

Mosquitoes are major vectors of arthropod-borne infectious diseases and are considered as the most dangerous vectors in the world. There are over 3500 known mosquito species which have been classified within 112 genera. They belong to subfamilies *Anophelinae* and *Culicinae* within family *Culicidae*. Examples of mosquito-borne viruses are shown in Table 1. *Aedes aegypti* and *Aedes albopictus*, are considered as two of the most important vectors of arboviruses in the world.

Originating from Sub-Saharan Africa, *Aedes aegypti* was introduced into Asia in the late 19th century and into the Americas during the slave trade in 1500s–1600s. Up until the late 20th century, *Aedes albopictus* was confined to Asia but has spread to the western hemisphere during a shipment of used tyres from Japan in 1985. These two mosquito species are vectors of important arboviruses, including yellow fever, dengue, Zika, chikungunya and Rift Valley fever (RVF) virus. Over the past thirty years, the distribution of *Aedes albopictus* has expanded to cover almost 40% of the world's landmass. Mathematical modelling predicts that the coming decades will see *Aedes* mosquitoes colonising major cities both in the United States of America and in Europe.

Culex and *Anopheles* mosquitoes are also important vectors for a range of arboviruses such as West Nile virus (WNV), Japanese encephalitis virus (JEV), St. Louis encephalitis virus (SLEV) and Rift Valley fever virus (RVFV). Mosquito vectors transmit a wide range of pathogenic viruses belonging to several genera (*Alphavirus*, *Flavivirus*, *Orthobunyavirus*, *Phlebovirus*, *Orbivirus*, *Seadornavirus*, *Vesiculovirus*). More than 90% of known human arboviruses are transmitted by mosquitoes.

Over the past two decades, insect-only or insect-specific viruses were also found in mosquito populations. These viruses include insect-specific flaviviruses (such as the cell-fusing agent virus and *Culex* flavivirus), insect specific phenuiviruses (such as Jonchet or Ferak virus), the insect-specific reoviruses (such as dinovernaviruses and cypoviruses) and the insect specific alphaviruses (Eilat virus), which can be all transmitted vertically (transovarial transmission) in these insect populations. The Insect-specific viruses cannot infect mammalian systems, and are restricted by a number of factors including temperature, the innate immune responses, or incorrect interaction with specific cell-cofactors. It has been suggested that these viruses could be used to control arbovirus

Table 1 Order of virus containing arboviruses with examples of viruses of medical or veterinary importance

Order	Family	Genus	Species	Biological vector	Genome organisation	Particle structure/symmetry
Asfuvirales	Asfarviridae	Asfivirus	African swine fever asfivirus	Ticks	dsDNA	Internal core, internal lipid layer, icosahedral capsid, outer lipid envelope
Articulavirales	Orthomyxoviridae	Thogotovirus	Thogoto thogotovirus	Ticks	6 ssRNA segments	Enveloped
		Quarantavirus	Quaranfil quarantavirus	Ticks	8 ssRNA segments	Enveloped
Bunyavirales	Nairoviridae	Orthonairovirus	Cribean Congo haemorrhagic fever orthonairovirus	Ticks	3 ssRNA segments	Spherical enveloped
	Peribunyaviridae	Orthobunyavirus	La Cross orthobunyavirus	Mosquitoes	3 ssRNA segments	Spherical enveloped
			Schmallenberg orthobunyavirus	Culicoides spp	3 ssRNA segments	Spherical enveloped
			Akabane orthobunyavirus	Culicoides spp	3 ssRNA segments	Spherical enveloped
			Rift Valley fever Phlebovirus	Mosquitoes	3 ssRNA segments	Spherical enveloped
Amarillovirales	Phenuiviridae	Phlebovirus	Rift Valley fever Phlebovirus	Mosquitoes	3 ssRNA segments	Spherical enveloped
	Flaviviridae	Flavivirus	Yellow fever flavivirus	Mosquitoes	Linear ssRNA	Enveloped, icosahedral nucleocapsid
			Dengue flavivirus	Mosquitoes	Linear ssRNA	Enveloped, icosahedral nucleocapsid
			Japanese encephalitis flavivirus	Mosquitoes	Linear ssRNA	Enveloped, icosahedral nucleocapsid
			Chikungunya alphavirus	Mosquitoes	Linear ssRNA	Spherical, enveloped icosahedral capsid
Martellivirales	Togaviridae	Alphavirus	Sindbis alphavirus	Mosquitoes	Linear ssRNA	Spherical, enveloped icosahedral capsid
			Middleburg alphavirus	Mosquitoes	Linear ssRNA	Spherical, enveloped icosahedral capsid
			Bleutongue orbivirus	Culicoides spp	10 segments of linear dsRNA	Icosahedral non-enveloped
			African horsesickness orbivirus	Culicoides spp	10 segments of linear dsRNA	Icosahedral non-enveloped
			Kemerovo orbivirus	Ticks	10 segments of linear dsRNA	Icosahedral non-enveloped
Reovirales	Reoviridae	Orbivirus	Colorado tick fever coltivirus	Ticks	12 segments of linear dsRNA	Icosahedral non-enveloped

	Rhabdoviridae	Vesiculovirus	Vesicular stomatitis virus	Ticks	Linear ssRNA	Membrane, bullet shaped

replication in the insects in a similar manner as *Wolbachia*. For instance, the cell fusing agent virus (CFAV) interferes with the replication of the 17D vaccine strain of YFV when mosquito cells are infected with CFAV prior to infection with YFV17D (unpublished observations) and the double-stranded (ds) RNA viruses can shut-down replication of single-stranded RNA viruses upon co-infecting the same cell.

Ticks are distributed worldwide. About 900 tick species were identified to date. They are classified into 3 families which are *Argasidae* (soft ticks, 183 species), *Ixodidae* (hard ticks, 683 species) and *Nuttalliellidae* (one species). Ticks are haematophagous ectoparasites which feed on vertebrate hosts, affecting both animal and human health. Ticks are vectors for a wide range of pathogens including bacteria, parasites and viruses. They are second to mosquitoes in terms of their importance as vectors of human arthropod-borne pathogens, but they represent the primary vectors for pathogens in animal health. In order to be transmitted by ticks, a pathogen must be trans-stadially transmitted, thus nymphs and adults are both major vectors. The tick population size is an important criterion which influences vector capacity. Less than 10% of known ticks are involved in field transmission of viruses. These ticks belong to genera *Ornithodoros* and *Argas* (soft ticks) within family *Argasidae* and genera *Ixodes*, *Haemaphysalis*, *Hyalomma*, *Amblyomma*, *Dermacentor*, *Rhipicephalus*, and *Boophilus* (hard ticks) within family *Ixodidae*. Certain ticks can transmit several viral species. One hundred and seventy tick-borne viruses have been identified to date (examples are given in [Table 1](#)).

Culicoides biting midges are haematophagous insects. They are members of the family *Ceratopogonidae*, order *Diptera*. Over 1368 species of *Culicoides* are known to date and they are found in geographical areas ranging from the temperate zones to the tropics. During their lifespan, female *Culicoides* midges can feed multiple times on hosts, allowing them to become infected and transmit arboviruses. The lifespan of biting midges is relatively short and only few adults survive longer than 10 days to 3 weeks. Most of the information known about the vector competence of *Culicoides* midges comes from studies of wild caught insects and laboratory studies mainly with established colonies of *Culicoides sonorensis* and *Culicoides nubeculosus*.

Culicoides midges are important vectors of economically important viral pathogens particularly the orbiviruses. Indeed, viruses belonging to the species *bluetongue virus*, *African horsesickness virus* and *Epizootic haemorrhagic disease virus* are all transmitted by *Culicoides* spp. vectors, although these viruses can also be transmitted vertically in their vertebrate hosts, or by an oral route and can cause fatal infections in certain carnivores. Some recently identified bluetongue viruses (serotypes 25 and 26) can be transmitted in the absence of adult *Culicoides*, which they appear to be incapable of infecting. Orbivirus infection of arthropods has little or no evident effect. Infection in vertebrates can vary from inapparent to fatal, depending on both the virus and the host species, age, immune status and stress factors. Severe BT disease is mostly restricted to certain breeds of sheep and some species of deer.

Depending on the strain, BTV may cause death or a variety of pathologies in sheep. These include haemorrhage, lameness, oedema, a transitory cyanotic appearance of the tongue (giving rise to the species name), nasal and mouth lesions, etc.; still others cause no overt pathology. BTV infection of cattle may show no signs of disease but can involve long-lived viraemias. AHSV and EHDV can cause severe pathology in their respective vertebrate hosts. Mortality rates in serologically naive populations can be over 98% (AHSV). BTV is teratogenic and can cause severe deformities (including dummy calf syndrome) due to a failure of the central nervous system to develop correctly after infection *in utero* in cattle and sheep. *Culicoides* midges are also vectors for orthobunyaviruses that are important in animal health (examples are shown in [Table 1](#)), including Akabane (AKA) and Schmallenberg (SB) virus.

Akabane virus was first isolated in Japan in the 1950s. Vectors of AKAV include *Culicoides imicola*, *C. brevitarsis*, *C. wadai*, and *C. minlei*. The geographical region affected by AKAV expanded to include Asia, the Middle East, Australia and Africa. Pathological manifestations on AKAV infections are observed during pregnancies leading to congenital malformations of the foetus in ruminants or encephalitis in new-borne calves. SBV was first identified in 2011 and spread rapidly throughout Europe. The virus has been reported in cattle, sheep and goats. It is believed to be transmitted by a range of *Culicoides* including *C. imicola*, *C. obsoletus*, *C. punctatus*, *C. dewulfi*, *C. lupicaris*, *C. newsteadi*, *C. nubeculosus*, *C. pulicaris*. SBV is responsible for congenital malformations of the foetus, stillbirths and failed pregnancies in cattle, sheep and goats. Adult *Culicoides* are also vectors of Ganjam virus in India (an isolate of *Nairobi sheep disease virus*, *Orthonairovirus*).

A biting midge identified as *Culicoides anophelis* has been documented since the 1950s in China and India. This biting midge feeds on mosquitoes of the genera *Aedes*, *Anopheles*, *Armigeres* and *Culex*. The wide host range of this midge makes it ideal to act as a biological vector, spreading viruses among various mosquito populations.

Sandflies which transmit viruses belong to genera *Lutzomyia* and *Phlebotomus* within subfamily *Phlebotominae*, in family *Psychodidae*. Sandflies of the genus *Phlebotomus* transmit important human pathogens such as Sandfly fever Naples virus (Mediterranean regions) or Chandipura virus (India). Sandflies of the genus *Lutzomyia* transmit arboviruses such as vesicular stomatitis virus (*Vesiculovirus*, *Rhabdoviridae*) or Changuinola virus (*Orbivirus*, *Reoviridae*).

Stomoxys flies transmit a number of viruses mechanically, particularly on their mouth parts and potentially by regurgitation of contaminated blood upon an onward blood meal. They have been incriminated in the mechanical transmission of a number of viruses including African swine fever, Equine infectious anemia (EIAV), West Nile and Rift Valley fever virus.

Co-Evolution of Viruses and Vectors: Vector-Only, Vector-Borne Viruses and Non-Vectored Viruses

There are different views as to whether arboviruses have co-evolved, or not, with their arthropod vectors. Looking at the genomes of the arboviruses in genera where tick-borne, mosquito-borne, sandfly-borne and/or *Culicoides*-borne viruses are encountered

(such as the flaviviruses or the orbiviruses) different observations are made. For the flaviviruses, the genomes of the insect-only viruses have a G + C of 50%–53%, the mosquito-borne flaviviruses have 47%–53%, and the tick-borne viruses 53%–54%. The “no known vector” flaviviruses (NKV) have a G/C content of 43%–48%, with the exception of Tamana bat virus (TABV) where the G + C content is ~38%. In the orbiviruses, the G + C content of the mosquito-borne orbiviruses range from 35% to 41%. The G + C content of the *Culicoides*-borne viruses range from 40% to 45% and the tick-borne orbiviruses have a G + C content of 52%–58%. The G + C content of arthropod vector genomes is ~56% for ticks, ~39%–42% for *Culicoides* and 35%–38% for mosquitoes. There are clear differences between the two genera. Only the tick-borne flaviviruses have a G + C content that is similar to that of their tick vectors (~57%). The G + C content of the insect only flaviviruses is very similar to that of tick-borne viruses and the G + C content of the mosquito-borne flaviviruses is largely overlapping with that of both the insect-only and tick-borne flaviviruses. This contrasts with orbiviruses where G + C content is very similar to that of their respective arthropod vector groups. These observations, among other findings, suggest that the orbivirus ancestors have coevolved with their vectors and may have originally been arthropod viruses that have adapted to their current vertebrate hosts.

Phylogenetic studies have classified the flaviviruses within four groups: two mosquito-borne groups, a tick-borne group and a group where viruses are considered as non-vectorized or as having no known vectors (NKV). Phylogenetic studies suggest that the mosquito-borne flaviviruses ‘root’ all of the other flaviviruses. Other studies suggest that NKV flaviviruses do not form a single phylogenetic group and that some of the NKV such as *Yokose* (YOK), *Sokoluk* (SOK), and *Entebbe bat* (ENT) virus cluster with the mosquito-borne flaviviruses, while other NKV viruses cluster with the tick-borne flaviviruses. It has also been suggested that YOKV, SOKV and ENTV are likely arboviruses, based dinucleotide frequencies in their genomes, as they do not seem to be specifically adapted to vertebrate hosts. Only *Tamana bat virus* (TABV) seems to be a vertebrate-specific virus, having a significantly lower CpG dinucleotide frequency than the insect-specific flaviviruses or arthropod/vertebrate flaviviruses.

Whether flaviviruses co-evolved with their arthropod vectors (i.e., originated before the split of invertebrates and vertebrates during evolution) or they originated in one or other group of hosts, followed by co-adaptation, remains debatable. Yet the high G + C content of most flavivirus genomes (including the insect-only viruses) raises questions as to whether the flaviviruses originated in ticks, or if this trait provided an advantage for the dispersal of flaviviruses among various arthropod vectors.

Certain insect-borne viruses are capable of infecting and replicating in tick cell lines. Semliki Forest virus (SFV) and Venezuelan equine encephalitis virus (VEEV), two mosquito-borne alphaviruses, can replicate well in tick cell lines *Rhipicephalus decoloratus* BDE/CTVM16 and *Rhipicephalus appendiculatus* RAE/CTVM1 cells. The G + C content of SFV genome is ~53% and that of VEEV is ~50%. Replication of 13 flaviviruses including Dengue virus (DENV), WNV, SLEV, YFV, tick-borne encephalitis virus (TBEV) Powassan virus (POWV), Louping ill virus (LIV), Negishi virus (NGV) and Langat virus (LGTV) was compared in mosquito and tick cell lines. The mosquito-borne viruses replicate efficiently in the mosquito cells and it was shown that WNV is capable of infecting and replicating in four tick cell lines. The tick-borne viruses replicate only in tick cell lines, except LGTV where signs of infection were observed in C6/36 cells. A previous study using Singh’s non-cloned *Ae. albopictus* cells (from which C6/36 were derived) failed to show replication of LGTV. NKV flaviviruses do not replicate in any arthropod cell lines. The G + C contents of DENV, SLEV and YFV are comprised between 45% and 50% whereas those of WNV, TBEV, POWV and LIV are up to 51%. Larvae and nymphs, but no adults, of *Amblyomma* species were shown experimentally to be susceptible for infection by WNV or SLEV. These results highlights important differences between different flaviviruses in terms of their capacity to potentially infect a distinct arthropod vectors.

Colorado tick fever virus (CTFV) and *Eyach virus* (EYAV) are two species within the genus *Coltivirus* (family *Reoviridae*). Replication of CTFV or EYAV in mosquito and/or tick cell lines has been explored. CTFV was grown in *Ae. albopictus* cells over 7 weeks and the titre reached ~10⁶ pfu/ml after 6 weeks, declining afterwards. As compared to titres of the same virus grown in mammalian cells (~10⁸ pfu/ml), the difference represents approximately 99% less virus in mosquito cells. Limited replication of EYAV-Fr578 was shown in C6/36 cells. A strain of Kemerovo virus (KEMV, genus *Orbivirus*) was grown both in *Ae. albopictus* C6/36 cells and *I. ricinus* tick cells. While titres of approximately 10⁷–10⁸ pfu/ml were observed in tick cells, titres of 10⁴ or less were obtained with C6/36 (unpublished data), that is to say 99.9%–99.99% less virus in mosquito cells. In summary, the lower levels of replication of a given animal arbovirus in a heterologous cell culture system suggest that a heterologous arthropod would not act as a likely vector for that particular virus.

Environmental/Anthropogenic Factors Contributing to Vector-Borne Virus Spread

Emerging/re-emerging viruses have been responsible for severe economic losses and heavy losses in terms of human lives. Over the past four decades the world has seen a number of epidemics, epizootics and pandemics which are thought to be due to emerging viruses.

The SARS-CoV2 pandemic, which has caused almost 1.2 million deaths to date, is one the most serious recent examples, yet human immunodeficiency virus remains the most devastating in terms of number of fatalities. Besides these examples, the bulk of emerging viruses are arboviruses. Their spread is linked to a number of factors and in particular, anthropogenic factors are among the most important including international trade and travel (movement of populations, animals and commercial goods), deforestation, afforestation, urbanisation and climate change induced by human activities.

The emergence of specific viruses can be facilitated by optimal climate conditions and the presence of local competent vectors. Tangible examples of arbovirus emergence are the epidemic of Chikungunya virus (CHIKV) in Italy in 2007 and south-eastern

France in 2010 and the return of autochthonous circulation of this virus in both countries in 2017. The Zika virus emerged causing an outbreak in the federated states of Micronesia in 2007 and in Brazil in 2015, while DENV emerged in India in 2015. Perhaps one of the most striking examples of economic damage caused by an arbovirus is bluetongue virus introduction into Europe. During the 20th century, BTV was endemic in sub-Saharan Africa. Since 1998, multiple introductions of BTV have occurred, initially in southern Europe, culminating in the BTV-8 outbreak during the summer of 2006 in Northern Europe, where transmission by the local midge populations, led to a devastating disease in the naive sheep and bovine herds in the region.

Replication and Transmission of Arboviruses in Their Arthropod Vector and the Role of Arthropods in Maintenance and Spread of the Virus

Arthropod vectors usually become persistently infected by the arboviruses they transmit (leading to persistent transmission). This is usually designated as “biological transmission” (persistent circulative propagative transmission in haematophagous arthropods). However, some viruses can be transmitted mechanically by biologically “non-competent” vectors.

Mechanical transmission of animal arboviruses by biologically non-competent arthropods shares some similarities with the non-circulative transmission of plant arboviruses. Both are non-persistent forms of transmission which are lost at a certain point after acquisition of the virus. However, specific interactions have been suggested between the animal virus and a haematophagous arthropod during mechanical transmission.

The poxviruses are poorly transmitted mechanically. Lumpy skin disease virus (LSDV) has been shown to be transmitted mechanically by *Aedes aegypti*. This mosquito harbours LSDV for up to 7 days. A distinct study showed that LSDV is not transmitted mechanically to susceptible animals by other insects including *Anopheles stephensi*, *Stomoxys calcitrans*, *Culicoides nubeculosus*, or *Culex quinquefasciatus*, although from a historical point of view *Stomoxys* flies were considered to play an important role in transmission. However, sheep and goat poxvirus, which is related to LSDV has been shown to be mechanically transmitted to susceptible hosts by *Stomoxys*. In summary, several studies suggest that transmission of LSDV by *Aedes aegypti*, is due to a far more elegant mode of transmission than a mere “dirty-pin” virus transfer. There have been suggestions that this parallels transmission of some plant viruses where specific associations and molecular interactions have been observed. *Stomoxys* flies can also mechanically transmit other animal arboviruses (ASFV, EIAV, WNV, RVFV).

Persistent transmission can occur when a virus crosses the gut wall, with or without replication within the gut cells, into the haemolymph, ending in salivary glands. Circulative non-propagative transmission is exclusively observed with plant viruses, in particular those belonging to families *Geminiviridae*, *Nanoviridae*, and *Luteoviridae*. It is believed that no known animal arboviruses use this mode of transmission. More than one study concluded the absence of replication of LSDV in *Amblyomma* and/or *Rhipicephalus* ticks, or derived cell lines. However, the virus was detected in the saliva of *Amblyomma hebraeum* and *Rhipicephalus appendiculatus*. Using anti-LSDV monoclonal antibodies, viral antigens were detected in the salivary glands, haemocytes, ganglia, ovaries, testes, fat bodies, and midgut of nymphs and adult ticks fed on LSDV infected cattle. Furthermore *R. appendiculatus* males (from a laboratory bred colony) fed on viremic cattle were found to transmit the virus to healthy cattle. Finally, of LSDV failed to replicate in *Rhipicephalus* tick cell lines. In conclusion, LSDV can be transmitted by *Rhipicephalus*, does not replicate in tick cells, even though LSDV antigen was detected in several tick organs. This situation is clearly distinct from simple mechanical transmission and points towards a form of circulative non-propagative transmission.

In biological transmission of animal viruses or the circulative propagative transmission of plant viruses, the pathogen is ingested as part of the meal (blood or sap). The virus then infects the midgut epithelium (single layer of cells) and replicates in the midgut cells, spreading into the haemocoel and other organs/tissues, including the salivary glands, where it undergoes further replication. The virus passes into the saliva of the vector and is delivered to the host upon feeding. While in insects blood meals are digested in the lumen of the gut, ticks are heterophagous, meaning that digestion of blood is intracellular within the midgut cells. Plant viruses which are transmitted by a circulative propagative mode, include those belonging to families *Reoviridae*, *Rhabdoviridae* and *Tospoviridae*. Like the animal arboviruses which are biologically transmitted by their haematophagous arthropods, these plant viruses replicate in their insect vectors.

The virus must cross/escape several barriers in the arthropod. The midgut in particular is the site of entry into the biologically competent vector. The “gut barrier”, is a major determinant of vector competence, controlling the virus both qualitatively and quantitatively and defines the “permissivity” and vector competence of an arthropod for a given virus. When environmental conditions favour rapid development of the arthropod exoskeleton, while internal organs are not fully developed, a ‘leaky gut’ may occur leading to viruses bypassing the gut barrier. Replication within midgut cells does not suffice for a virus transmission by haematophagous arthropods. The virus must also disseminate to the other tissues in the vector, in particular to the salivary glands.

In studies conducted with yellow fever virus vaccine strain YFV-17D in *Aedes aegypti* mosquitoes, it has been shown that the virus replicates in the mid gut cells (with 10 times less viral RNA of YFV-17D produced, compared to wild type YFV) but fails to disseminate onwards. Upon intrathoracic injection of mosquitoes with YFV-17D, the virus efficiently infects secondary tissues including legs and salivary glands. Thus, the outcome of the interactions between the virus and the gut barrier determines the chances of dissemination and onward transmission. Not all vaccine arbovirus strains are non-transmissible by arthropod vectors. For example, *Culicoides* midges can transmit live-attenuated vaccines of the orbiviruses. Although attenuated, these vaccines act like wild type viruses in terms of their transmission from inoculated (vaccinated) to healthy animals and have been shown to persist, become disseminated and can cause infection/disease in the field.

The virus quasispecies found in infectious blood meals are subjected to a “bottleneck” in the midgut and it is supposed that infection of the midgut will require a relatively high titre of virus to infect the midgut cells. Disseminated viruses from the midgut are subjected to a second bottleneck in the salivary glands, due to particular genotypes of the virus being maladapted to salivary glands, or the viral population is subjected to non-selective reduction.

Identification of receptors of arboviruses on gut cells and other organs is work in progress. Data concerning receptors of arboviruses in their arthropod vectors come mainly from cell culture studies. Poorly characterized receptors have been identified, such as those for DENV (polypeptides ranging from 40 to 80 kDa) and VEEV (a major polypeptide of 32 kDa). For DENV one of the most promising potential receptors in mosquito cells is a 35 kDa protein known as prohibitin. Treating insect cells with anti-prohibitin antibodies or silencing its expression using siRNAs, significantly reduced DENV binding. Yet arthropod cell cultures are polyclonal with poorly characterized tissue origins. Receptors of CHIKV have been identified in larvae and adults of *Aedes aegypti* to be in the midgut brush border membrane. They were identified as glycoproteins ranging in size from 24 to 62 kDa. Identified receptors in arthropod cells are distinct from their counterparts in vertebrate cells. The outer capsid proteins (VP2 and VP5) of bluetongue virus are responsible for cell attachment and infection of mammalian cells. However, in *Culicoides* cell cultures, or adult *Culicoides* (via an oral route), proteolytic cleavage of VP2 can significantly enhance the infectivity of the virus. Complete removal of these outer capsid proteins massively reduces or abolishes the infectivity of the resulting BTV core particles for the mammalian BHK or CHO cells respectively. However, BTV core particles retain the same infectivity as the intact virus particles for *Culicoides* cells, suggesting the availability of alternative receptors and cell entry mechanisms in the insect vectors.

Viruses must survive the arthropods’ behavioral characteristics. In contrast to mosquitoes that can take several blood meals during the same life stage (adult female), hard ticks feed only once before moulting, meaning that viruses need to survive moulting, in order to persist into the next life stage and the opportunity to be transmitted. Several months can pass between two tick life-stages. Tick-borne viruses can persist by infecting tissues which do not undergo histolysis during moulting. Some tick-borne viruses can also be transmitted transovarially and/or trans-sexually to the next generation. Vertical transmission in ticks and insects and transmission by co-feeding between ticks contribute to the natural survival and spread of the arboviruses.

The local abundance of vectors and the genetics of the virus can both influence transmissibility, as seen for example when CHIKV switched vectors from *Aedes aegypti* to *Aedes albopictus* in 2004. A single amino acid substitution A226V in the E1 envelope glycoprotein of CHIKV helped the virus to move to its new vector. The mutation in the E1 glycoprotein lowers the threshold of viraemia necessary to infect *Ae. albopictus* mosquitoes. A change at this position in Semliki Forest virus (P226S) was previously reported to free the virus from dependence on cholesterol for cell entry.

Certain arboviruses can be sexually (horizontally) transmitted between arthropods. The male mosquitoes acquire the virus from an infected female. Upon mating, the male further transmits the virus to non-infected females, in which the virus infects the oocytes, leading to vertical transmission to the offspring. This was shown for La Crosse virus in *Aedes triseriatus* and Dengue and Zika virus in *Aedes albopictus*.

Vertical transmission has been proposed as a maintenance mechanism during adverse conditions for some arboviruses. Dengue, Japanese encephalitis and St. Louis encephalitis virus are vertically transmitted when the fully formed egg of *Aedes albopictus* is oviposited. Vertical transmission of RVFV (*Phlebovirus*) was observed through the eggs of *Aedes* spp (subgenus *Neomelanimon*). It has been suggested that this mechanism, known as trans-ovum transmission could be common to all mosquito-borne flaviviruses. Transovarial transmission, a variant form of vertical transmission, occurs when germinal cells of a female mosquito are infected with a given virus, hence the majority of offspring will be infected. The lifespan of mosquitoes is dependent on different factors. Male mosquitoes are not haematophagous and feed on plant nectar. They live up to 7 days on average. The average lifespan of a female mosquito is around 6 weeks. Female mosquitoes are haematophagous and depending on abundance and adequacy of hosts, female mosquitoes can live up to 5 months.

Virus–Vector Interactions and Role of the Arthropod Innate Immune Response

Virus–vector interactions dictate the outcome of infections, replication, dissemination and onward transmission.

Salivary components facilitate vasodilation in order to promote blood flow, promote replication, suppress host immunity and pain and prevent blood coagulation and haemostasis. Arthropod saliva increases disease severity. The physiological activities of salivary components have been linked to promoting viral replication and dissemination and pathogenesis in the host bitten by the arthropod. Mosquito saliva promotes a TH2 immune response while induction of this type of response is less prominent by tick saliva. Mosquito saliva suppresses type-I IFN signalling in the host thus promoting replication. Enhancement of replication of arboviruses by arthropod salivary components was observed with orthobunyaviruses (La Crosse encephalitis and Cache Valley virus), phleboviruses (RVFV), ASFV, and flaviviruses (DENV). The sensitivity response to insect bites attracts cellular components of the immune system to the site of biting and infection. Bluetongue virus, can infect these cells, promoting virus replication and the early dissemination within the vertebrate host.

Arboviruses seem to contribute to the modification of arthropods’ behavior. For example, *Aedes aegypti* infected with DENV experience longer probing times and feed for longer durations. This contrast with studies of RVFV-infected *Culex pipiens*, where mosquitoes with non-disseminated infection feed for significantly longer times than mosquitoes with fully disseminated infection.

Determinants of the vector competence include the innate immune response within the infected arthropod. These responses include RNA interference, Jak-STAT pathway (Vago), Nf-κB, Imd and Toll and autophagy. RNA interference is the predominant

pathway which controls virus replication in infected arthropod cells. Double-stranded RNA (dsRNA) triggers the RNAi response. Long dsRNA is processed by the mediator Dicer-2 which cleaves the dsRNA into 21–23 long short interfering RNAs designated siRNA or viral interfering RNAs (viRNAs). The guide strand of the viRNA binds to its foot-print in the viral mRNA. Upon binding, the dsRNA region is processed by Ago-2 which cleaves the mRNA inactivating it. RNAi is a common response in various arthropods. Double-stranded RNA presence in cells indicates viral replication. viRNAs have been detected in arthropod infected cells with a wide range of viruses as diverse as CHIKV (*Alphavirus*), DENV (*Flavivirus*), or BTV (*Orbivirus*) and St. Croix River virus (*Orbivirus*).

Environmental conditions such as the extrinsic temperature influence the RNAi response. Thus, lower temperatures supposedly reduce the efficacy of the RNAi response. For single stranded RNA viruses, the virus replication mechanism includes the formation of a dsRNA replication intermediate. Virus with dsRNA genomes have their dsRNA sheltered at all times within the core particles, shielding it from detection by the innate immune system. Unlike plants, which express RNA-dependent RNA polymerase (RDRP), insects lack an RDRP. The RDRP is necessary for the amplification of the RNAi response, by continuously generating viRNAs. dsRNA intermediates of ssRNA viruses may be accessible to Dicer, yet for dsRNA viruses where the genome is sheltered in the compact core particles, an accessible form of dsRNA might be generated from positive sense mRNA by the viral RDRP.

The genomes of arboviruses can become incorporated as cDNA copies into the genomes of their arthropod vectors. There is potential for these copies to act as sources of viral RNA sequences that can initiate a silencing response to infecting virus. If these sequences become incorporated into the arthropod germ line they can in practice act to generate a trans generational immune memory response.

Facing this efficient innate immune response, arboviruses have evolved strategies to counter RNAi response. One of the well-known strategies is the synthesis of decoy RNAs such as the flavivirus (such as DENV and WNV) sRNAs which interact with the RNAi machinery, sequestering RNAi mediators such as Dicer and Ago. Plant viruses have evolved other strategies by expressing proteins designated as viral suppressors of RNA silencing (VSRs), which bind to and sequester viRNAs from the RNAi machinery. Many arbovirologists do not support the presence of such a mechanism in animal arboviruses, despite that NS4B of DENV has been shown to act as a VSR using a reporter gene assay.

Other innate immune pathways include Jak-STAT, Toll and IMD. These pathways have been shown to be activated in response to Sindbis virus and DENV in *Ae. Aegypti* and WNV in *Culex pipiens*. Infection of *Aedes albopictus*-derived U4.4 mosquito cells by SFV activated STAT/IMD pathway, but not Toll. CHIKV repressed the activity of Toll signalling pathway in vitro. Neither JAK/STAT, IMD nor Toll pathways were found to mediate antiviral activities to CHIKV infection.

BTV replicates efficiently in *Culicoides* biting midges or derived cells lines. Until 2008 there were 24 known serotypes of BTV. However, since 2008 several novel serotypes have been identified some of which do not replicate in live adult *Culicoides* or a derived cell line. We have identified that their restriction in *Culicoides* cells is mediated by 4 genomes segments (segments 1,2,3 and 7) each of which individually restricts replication when included by reverse genetics in the backbone of a vector transmitted BTV. This group of non-vectored BTVs is transmitted horizontally between animals by direct contact, likely by an oral-fecal mechanism.

Co-Infection of Arthropods With Symbiotic Bacteria and How It Influences Virus Replication

Wolbachia is an intracellular gram-negative bacteria which was first identified in 1924 in *Culex pipiens*. It naturally infects more than 65% of arthropod species and *Wolbachia* genetic lineages are typically associated with a single host species. Despite infecting their hosts, a number of *Wolbachia* strains protect their host against several viruses including DENV, CHIKV, WNV and ZIKV in mosquitoes, *Drosophila C virus* (DCV) and *flock house virus* in *Drosophila*, although the mechanisms involved are not known. *Wolbachia* has been assessed as a novel alternative biological control agent in mosquitoes, to limit their ability to transmit flaviviruses and potentially reduce their life span. Of the two main dengue vectors, only *Ae. albopictus* has a natural *Wolbachia* infection in the wild, with two strains: wAlbA and wAlbB. No natural association is known of *Wolbachia* with *Ae. Aegypti* mosquito (primary species responsible for transmitting DENV). However, there are currently three *Wolbachia* transinfections of *Ae. aegypti*, with wAlbB (from *Aedes albopictus*) and another two strains wMel and wMelPop (from *Drosophila melanogaster*). These strains have been used to infect a variety of mosquitoes, and the resulting host manipulations are diverse, with some proving useful for mosquito control purposes. Strain wMel is a non-virulent strain while wMelPop is a virulent strain shortening the life in *Aedes aegypti*. Both wMel and wMelPop successfully inhibited the ability of *Ae. Aegypti* to transmit DENV (replication and dissemination); the more virulent wMelPop showed higher efficacy in limiting DENV replication.

There are two potential explanations as to how *Wolbachia* interferes with virus replication. The first being a competition for host resources between *Wolbachia* and viruses. Previous studies showed that *Wolbachia* modulates the host cholesterol levels in *D. melanogaster* which leads to protection against DCV. *Wolbachia* blocks less effectively virus replication when cholesterol levels are significantly higher in *Drosophila*. During DENV infection, specific lipid classes become enriched in the mosquitoes. *Wolbachia* causes certain lipid classes to be depleted and likely produces cellular lipid environment that inhibits replication of mosquito-borne viruses.

The second explanation involves activation of immune genes. *Wolbachia* induces reactive oxygen species (ROS)-dependent activation of the Toll pathway. Oxidative stress is induced upon infection with *Wolbachia* and an increased level of reactive oxygen is observed. Antimicrobial peptides defensins and cecropins are activated by ROS and are involved in the inhibition of DENV replication. *Wolbachia* downregulates chromodomain helicase DNA-binding protein of *Ae. aegypti*. Previous studies showed

significant downregulation of AeCHD7 in the presence of *Wolbachia* in female mosquitoes only. Levels of AeCHD7 are significantly increased during DENV infection, while depletion of AeCHD7 significantly reduces DENV replication.

Further studies identified induction of Vago by *Wolbachia* wMelPop as a mechanism of inhibition of DENV replication in *Aedes aegypti* cells. *Wolbachia* suppresses the replication of WNV in *Culex quinquefasciatus*, that of DENV, CHIKV, and ZIKV in *Ae. Aegypti* but has no significant effect of YFV in *Ae. aegypti* or WNV in *Culex tarsalis*.

Role of the Vector in the Genetic Diversity of Animal Arboviruses

Mosquitoes, sandflies, *Culicoides* and ticks do not have the same lifecycles and lifestyles. The tick-borne viruses are longer associated with their vectors than the insect-borne viruses, due to a much longer vector life span. The arbovirus subpopulations that are generated during infection of mammals/arthropods are likely to influence the outcome of infection and onward transmission. Although alternation between host and vector constrains the evolution of the majority of arboviruses, serially passaged animal arboviruses in their vectors leads to host specialisation. For example, VEEV serially passaged in live mosquitoes, induced low levels of virameia in mice after feeding on the animals. However, the serially passaged virus resulted in higher rates of infection in mosquitoes, as compared to the first passage and had a single synonymous substitution in the non-structural protein nsP1 (viral capping enzyme). The frequency of the viral population having this substitution increased by the eight passage becoming frequent at the tenth passage.

Serial passages of RVFV in *Aedes aegypti* mosquito cells led to deletion of large parts of the virulence factor NSs protein and this was observed by the 10th passage. This virus was non-virulent in mice acting like a protective vaccine upon challenge with wild type RVFV.

Hyalomma marginatum tick-adapted TBEV (17 serial passages) is less virulent to mice than the parental strain. Fifteen nucleotide substitutions, six of which were non-synonymous (resulting in changes in protein sequences for E, prM, NS2A and NS4A) were identified in the genome of the tick-adapted virus. Changes were also linked to stronger/lower affinities of the virus to cellular heparan sulphate and the binding of virions to cellular glycosaminoglycans.

The genome plasticity of CCHFV was assessed in a tick vector and an animal host. Nymphs of *Hyalomma marginatum* tick were fed on CCHFV-infected mice and conserved for one year after moulting into the adult stage. NGS sequencing identified substitutions only in CCHFV from ticks but not mice. Mutations were distributed on all three genome segments and were common to more than one tick. The genetic diversity of CCHFV is larger in ticks than in mice.

Passaging orbiviruses sequentially in mammalian cells has been the basis of attenuating these viruses. For instance, serially passaged BTV in BHK-21 cells significantly reduces its virulence in mice. Passaging this virus once in cells derived from the embryos of *Culicoides* midges is enough to restore virulence and this has been associated with expanding the genetic variability in insect cells.

Glossary

Dysbiosis Alteration of the composition of the normal microbiome.

Human microbiome The collection of bacteria, archaea, micro-eukaryotes and viruses that colonize the human body.

Human virome The entire collection of viruses that inhabit our body. The virome is part of the human microbiome.

Next generation sequencing New technologies that allow for massively parallel sequencing of nucleic acids (also known as high-throughput sequencing).

Prophage A phage genome that is incorporated into the bacterial host chromosome.

Shotgun sequencing The sequencing of entire chromosomes and entire genomes based on the production of random fragments of DNA.

Viral metagenomics The analysis of the whole viral genomes in a particular sample.

Definition of the Human Virome

The human body shelters a complex, dynamic and abundant microbial community composed of bacteria, archaea, microeukaryotes (fungi and protozoa) and viruses that contribute to human health and disease. These microorganisms constitute what is called the microbiome and by extension, the viral component of this microbiome is called the virome. The human virome is basically made of all the viruses that are found at the surface or inside our body. It thus includes eukaryotic viruses infecting our cells or members of our eukaryotic microbiome, viruses of archaea and viruses of bacteria (also called bacteriophages or phages). Beside free virions, the human virome also includes all viruses and virus-derived elements that are either integrated within the host chromosome (human endogenous retroviruses, proviruses and prophages) or maintained extrachromosomally within the cells (episomes).

Eukaryotic viruses infecting our cells have evident role in human health and disease. Viral infections lead to a wide range of clinical manifestation, from asymptomatic to severe, or even fatal conditions. During lytic infection, the viral genome is actively replicated and the release of new progeny virus particles often leads to the lysis of the host cell. In case of resolutive infection, virus is cleared by host immunity whereas in case of persistent infection, virus continues to replicate (chronic infection) or is staying quiescent without replication (latent infection). Latent viruses have the ability to reactivate into a lytic form. Human papillomaviruses (HPV), polyomaviruses, adenoviruses or herpesviruses are persistent viruses with the capacity to promote cell transformation and induce cancer development. Viral integration may also have significant impact on host evolution if the virus infects the germ lines. Indeed, Human Endogenous Retroviruses (HERVs), which represent more than 8% of the human genome, are remnants of exogenous retroviruses that have been fixed in the human genome. They are transmitted through generations and ubiquitously transcribed in normal tissues. Some viral proteins of endogenous viruses have given important physiological functions to the host such as syncytins that are essential for placental morphogenesis in mammals.

Bacteriophages constitute the major fraction of the human virome. They are particularly abundant at body barrier sites such as the gastrointestinal tract or the oropharynx where the density of their bacterial host is high ([Table 1](#)).

Bacteriophages infect bacterial cells either via lytic (for virulent viruses) or lysogenic (for temperate viruses) cycles. Lytic cycle leads to host cell lysis and viral production through diversion of the cellular host machineries. In contrast, lysogenic cycle leads to the integration of viral genome into bacterial genome. The latent bacteriophage is then called a prophage and is vertically transmitted after cell division. Environmental stressors can induce lytic activation of integrated prophages. Viral infection thus

Table 1 Abundances of virus-like particles in different body systems. Abundances of free virions in different compartments of the human body have been measured experimentally by direct counts using epifluorescence microscopy (eFM) or flow cytometry (FC) after filtration and staining of the viral nucleic acids protected by the capsid or *in-silico* quantification using spiked exogenous virus as internal control (IC)

Body system	Sample	Number of virus-like particles	Pathology	Method
Gastrointestinal tract	Stools	10^8 – 10^{10} /g	–	eFM, IC
	Gut mucosa	10^9 /biopsy	–	eFM
Circulatory	Blood	10^5 /ml	–	eFM
Oropharynx	Saliva	10^8 /ml	–	eFM
	Dental plaque	10^7 /mg	–	eFM
	Maxillary sinus flush	10^9 /ml	Chronic rhinosinusitis	FC
Urinary tract	Urine	10^7 /ml	Controls and patients with urinary tract infection	eFM
Tegumentary	Skin	10^6 /cm ²	–	eFM

regulates bacterial community composition and structure as well as bacterial function by providing genes that may be involved in bacterial fitness, pathogenesis and adaptation to changing environments. Bacteriophages can also indirectly influence human health by maintaining homeostasis of the indigenous bacterial community through the lysis of bacterial pathogens or in contrast, by inducing dysbiosis through predation on beneficial bacterial strains.

Only scarce information is currently available for viruses that infect other members of the human microbiome such as protozoans, fungi or archaea in the body compartments of asymptomatic individuals. These correspond to a largely unexplored area of the human virome and are therefore not included in this article.

Technological Development and Limits for the Description of the Human Virome

Advances in virology have often been driven by technological developments (Fig. 1) and nearly 40 years after the first description of viruses, it became possible to visualize their structure with electron microscopy. Cell culture for growing viruses was another technological breakthrough as it allowed sufficient viral material to be recovered for the development of biochemical virology in the 60's and subsequent molecular biology in the 80's.

In the last 10 years, the study of the human virome has been largely facilitated by the development of next-generation sequencing (NGS) technologies even though it still lags far behind those addressing the bacterial component of the human microbiome, as done within the Human Microbiome Project (HMP) (see “Relevant Websites section”). This is partly due to the fact that viruses, in contrast to bacteria, lack universal phylogenetic markers such as the 16S rRNA gene. Current protocols for generating a viral metagenome then rely on the high-throughput shotgun sequencing of viral nucleic acids extracted after enrichment/purification of circulating viral particles by using filtration and (ultra)centrifugation steps and further digestion of the non-encapsidated contaminant nucleic acids (e.g., human, bacterial) with nucleases. Using such protocols, latent viruses (prophages and proviruses) that stably reside within cells (in integrated or episomal forms) are largely missed and their diversity/functionality is probably underestimated. Other poorly described members of the human virome in healthy individuals are large dsDNA viruses whose recovery is prevented by filtration and RNA viruses, because most viral metagenomic studies conducted on RNA viruses were targeting diseased individuals. Thus, many eukaryotic viruses (both DNA and RNA viruses), including potential pathogens, have yet to be discovered.

Finally, there is still a high proportion of the reads obtained after sequencing that do not have homologs in public databases. This represents a major obstacle for accurate description of the human virome based on taxonomic composition. As more viruses are being isolated and functionally characterized using more traditional methods (cell culture, molecular biology, Fig. 1) and their genomes are added to the databases, a more precise and complete overview of the human virome will emerge.

Composition and Diversity of the Human Virome by Body Compartments

So far, most metagenomic works have focused on the analysis of the composition and the diversity of viruses at individual body sites such as the gastrointestinal, respiratory and genito-urinary tracts, the oral cavity, skin and blood. The distribution of the main viral families detected in these major human body sites is presented in Fig. 2.

As done for microbial communities, further initiatives analyzing the differences in viral communities between body sites (body barriers or systemic compartments), geographic sites, disease states or age groups should be largely developed in the future. Results from such studies will certainly deepen our knowledge of the factors that influence the composition, diversity and dynamics of the human virome in healthy individuals.

Gastrointestinal Tract Virome

Gut microbiome is so far the most studied microbial community in healthy human, due to its known or suspected roles in a broad range of homeostatic physiological functions and inflammatory bowel diseases, and its large biomass which makes possible reliable

Fig. 1 Timeline of the main technological advances in virology.

Fig. 2 Distribution of the main viral families found in major human body sites. Each viral group is represented with a unique color. Modified from Popgeorgiev, N., Temmam, S., Raoult, D., Desnues, C., 2013. Describing the silent human virome with an emphasis on giant viruses. Intervirology 56, 395–412, with permission.

sampling. The gastrointestinal tract is a highly heterogeneous environment harboring different microbial and viral communities both across its length and between the mucosa and lumen. Most analyses of gut viromes used samples from feces, due to obvious convenience of sampling. However, the beginning of the gastrointestinal tract in humans and pigs display a much higher and more stable proportion of bacteriophages. At the mucosal epithelium, phages accumulate at a concentration 10 times higher than bacteria. Viruses are highly abundant in the gut, with a large predominance of bacteriophages compared to eukaryotic viruses. Phage communities are primarily composed of tailed bacterial viruses (order Caudovirales), of the *Myoviridae*, *Podoviridae*, *Siphoviridae* families, and members of the *Microviridae* family. Other bacteriophage families, such as *Corticoviridae*, *Inoviridae* and *Tectiviridae*, have been identified with much lower abundances, as well as rare archaeal viruses (mainly from *Lipothrixviridae*). But nowadays, the majority of the gut virome (up to 85%) is still composed by unclassified or unknown viruses. Nevertheless, recent studies demonstrate that such difficulties could be overcome through bioinformatics efforts, as confirmed by the recent discovery within this unknown fraction of the novel bacteriophage, named α Assphage. Since then, data mining showed that α Ass-like phages are very abundant and highly prevalent in human populations worldwide especially those living in industrial areas. Successful isolation of a α Assphage was achieved in 2018 on *Bacteroides intestinalis*. Although this α Assphage isolate is a virulent podophage, it does not hamper proliferation and stably replicates along with its bacterial host for many generations. Going further, recent investigations demonstrate that α Assphage is a long-term human partner that has co-evolved with the human lineage.

Phage colonization of the gut occurs very early after (and possibly before) the birth, dynamically with their bacterial hosts/preys, coming from the diet and the environment, with primo-colonizers principally composed by *Caudovirales*. A recent study, using high depth sequencing technology, described high richness and diversity of first viral populations, coupled with high taxonomic instability, certainly due to the low colonization of the corresponding microbial hosts. During the first months of life, this diversity dramatically decreases, and the virome evolves toward a composition characterized by a higher relative abundance of *Microviridae* around 24 months of life/age. In healthy adult, gut virome is stable for long periods, even though phage communities are very different between individuals. Despite this individual specificity, a tiny core of bacteriophage core “species” seems to be widely distributed and conserved within the human population. Environmental exposure, diets, habits, and even genetics are suspected to play a role in shaping these communities, but the mechanisms and processes contributing to interpersonal phage dynamics are still unclear.

In contrast to bacteriophages, the eukaryotic virome is acquired after birth through environmental exposures and, as a consequence, eukaryotic virus diversity increases over time. Between 0 and 2 years, the most prevalent RNA viruses are enterovirus, parechovirus, tobamovirus and sapovirus and anelloviruses for DNA viruses. Anelloviruses are rarely detected earlier than 3 months of age and their abundance increase until peaking at 6–12 months and then decrease at 18 months of age. Others eukaryotic DNA viral families that have been less frequently detected by metagenomic studies are *Geminiviridae*, *Herpesviridae*, *Nanoviridae*, *Papillomaviridae*, *Poxviridae*, *Parvoviridae*, *Adenoviridae*, *Polyomaviridae*, *Circoviridae* and families of large dsDNA viruses such as *Marseilleviridae* and *Mimiviridae*. Eukaryotic RNA viruses in the gut of healthy adults have been thus far largely ignored by metagenomic sequencing analyses but this community seems to be dominated by plant- and insect-viruses, likely originating from the food.

Skin Virome

The human skin represents one of the first line of defense against external pathogens. It is composed of diverse microenvironments with distinct physicochemical parameters (temperature, moisture, pH, *etc.*) that strongly influence and shape microbial composition and function. Healthy skin usually shows low viral biomass and, depending on the study, either phages or eukaryotic DNA viruses dominate the viral community. Overall, the skin virome is highly variable across anatomical location and individuals with a relative stability of the phage community across time whereas eukaryotic DNA viruses are the most transient members of the skin community. Most phage sequences detected from the skin virome cannot be classified, even at the family level. Among those that can be taxonomically identified, most belong to the *Myoviridae* and *Siphoviridae* families. A core phageome of *Propionibacterium*, *Staphylococcus* and *Streptococcus* phages infecting the main bacterial genera present on human skin, is often detected between and within individuals. Their detection may be linked to the lysogenic nature of the infection as the majority of the skin bacteriophages were predicted to be temperate. Dominant families of eukaryotic DNA viruses were *Papillomaviridae*, *Polyomaviridae* and *Circoviridae*. Other DNA virus families that can be detected are *Poxviridae*, *Phycodnaviridae*, *Mimiviridae*, *Herpesviridae*, *Adenoviridae* and *Anelloviridae*. In few individuals and at particular body sites, a bloom of potential human pathogens can be observed in absence of clinical lesions. In addition, an expansion of the eukaryotic skin virome has been observed in immunodeficient patients compared to controls. This suggests, to some extent, an immune control of the skin colonization and infection. Finally, only scarce studies have described RNA viruses from the skin of healthy individuals so this group remains largely uncharacterized. In a recent study, RNA viromes were generated but most of the sequences mapped to DNA viruses of the *Papillomaviridae* and *Polyomaviridae* families, suggesting active replication state of these viruses. Only few other sequences were detected and these were related to *Coronaviridae*, *Picornaviridae*, *Orthomyxoviridae* and *Paramyxoviridae*.

Oral Cavity and Respiratory Tract Viromes

Similarly to the skin, the oral cavity is a highly heterogeneous environment displaying aerobic and anaerobic environmental niches made of soft (palatine, tongue) and hard (teeth) tissues, mucosa and biofilms that are all cleaned by saliva. The virome from the

oral cavity is dominated by phages of the *Siphoviridae*, *Myoviridae* and *Podoviridae* families and the composition of the oral virome is highly stable over time and personalized among individuals and, to some extent, gender specific due to host factors, such as hormones. Oral viromes were more similar between people having the same diet and between people sharing the same household or family. The core oral virome consisting of phages and prophages infecting *Streptococcus* species and human herpesvirus 7 has been identified, at least in the Western society. Compared to phages, the proportion of eukaryotic viruses in the oral cavity virome of healthy individuals is far less abundant. Apart from herpesviruses, sequence homologs of papillomaviruses, anelloviruses, poxviruses, phycodnaviruses, mimiviruses and few RNA viruses have been occasionally detected and their abundance might increase in particular stressful situations such as antibiotic intake or periodontal disease.

The virome from the respiratory tract has been mainly studied in the context of naso-pharyngeal and pulmonary pathologies as sampling procedures might be invasive particularly those targeting the lower airway. It thus mostly focused on the detection of potentially pathogenic eukaryotic viruses whose presence and abundance were highly variable among studies mostly due to the season of sampling, the viruses that were circulating in those particular geographical regions and the sample type. Very recently, novel circular Rep-encoding single-stranded DNA (CRESS) viruses were selectively identified in the human oro-respiratory tract and proposed as a new *Redondoviridae* family. Although the redondovirus prevalence among healthy and diseased subjects was similar, viral burden was observed in case of periodontal diseases.

Blood Virome

Early metagenomic studies have demonstrated that the human blood may represent a substantial reservoir of novel viruses that may represent a risk for the safety of blood products. Recently, a large screening of virus sequences in shotgun sequencing data from human blood cells from 8240 individuals identified the presence of 94 different viruses including 19 human viruses in 42 % of the participants. High prevalence of human herpesviruses and anelloviruses was detected and differences in viral prevalence depended on age, ancestry and sex with a greater prevalence of viruses in men than in women. This observation may be related to gender susceptibility to infection or to different innate and adaptive immune responses. Anelloviruses are ssDNA viruses belonging to the *Anelloviridae* family and include Torque Teno Viruses (TTVs), TTV-like viruses, SEN viruses, TTV midi viruses and TTV-like mini viruses. Anelloviruses are commonly detected in peripheral blood samples and present a high level of genomic heterogeneity. They are transmitted by transfusion and their abundance could serve as a biomarker of immune competence and as predictor of adverse outcomes after organ transplantation. Their role in human physiology and disease is still unclear but they are often considered as non-pathogenic commensals. Other eukaryotic DNA viruses are episodically detected in the blood of healthy humans and these belong to the *Papillomaviridae*, *Polyomaviridae*, *Parvoviridae*, *Adenoviridae*, *Poxviridae*, *Mimiviridae*, *Marseilleviridae* and *Phycodnaviridae* families, and Mollivirus genus.

Among eukaryotic RNA viruses, human pegivirus (HPgV) of the *Flaviviridae* family, formerly known as GB virus C (GBV-C) is highly prevalent among human populations and can be transmitted through parenteral, sexual, or mother-to-infant routes. Co-infection of HPgV with immunodeficiency virus (HIV) delays progression to AIDS as well as it improves survival to Ebola infection possibly by preventing aberrant immune activation. Other RNA viruses detected in the blood of asymptomatic individuals belong to the *Picornaviridae* and *Rhabdoviridae* families.

Phage sequences belonging to the *Myoviridae*, *Podoviridae*, *Siphoviridae*, *Microviridae*, and *Inoviridae* families are also frequently detected in blood samples of healthy individuals and higher sequence abundances have been detected in case of pathology. Although phage sequences in the human circulation may derive from contaminations, phage translocation and phage transcytosis events support the establishment of the intrabody phageome. How these phages might have reached the circulation and their role in the human body is discussed in the next article.

Genital and Urinary Tract Viromes

Viruses from the genito-urinary environment are only poorly described. The vaginal eukaryotic DNA virome of pregnant and non-pregnant women is dominated by viruses from the *Papillomaviridae* family, with half of them being only found in this body compartment whereas the others are shared with the skin, gastrointestinal tract and oral cavity. Other viral families such as *Polyomaviridae*, *Herpesviridae*, *Poxviridae*, *Adenoviridae* and *Anelloviridae* are also occasionally detected. A higher vaginal viral diversity is associated with pre-birth term in pregnant women. Human papillomaviruses, herpesviruses and polyomaviruses are also found in urine samples without significant differences in prevalence between men and women. The urine virome also contains a large proportion of bacteriophage sequences whose majority are probably lysogenic based on the high proportion of integrases identified in their sequences. According to a recent study on women with or without lower urinary tract infection symptoms, 86% of urinary bacterial genome contained at least one phage sequence most of them being novel. The detection of similar phage sequences among different women suggests the presence of a core bladder phageome whose role in health and disease remains to be elucidated.

Implication of the Virome in Human Health and Immunity

Numerous reports have highlighted the potential role of the virome in resilience and human health although the molecular and physiological mechanisms underlying these interactions remain largely unknown. Besides the evident role

of bacteriophages in regulating the bacterial microbiome, there is increasing evidence that this fraction of the virome may also interact with the human immune system by inducing a humoral response and triggering innate and adaptive immune responses. Circulating bacteriophages can interact directly with human antibodies, be engulfed by dendritic cells *in vitro*, and inhibit activation and proliferation of human T cells *in vitro*. Prophages may also change bacterial recognition by the immune system by modifying the outer membrane lipopolysaccharide (LPS). Few years ago, the bacteriophage adherence to mucus (BAM) has been proposed as a model of non-host derived innate immunity mediated by bacteriophages. This model relies on the observation that bacteriophages accumulate to high densities at the mucosal surfaces. According to this model, lytic phages able to transiently bind the mucin-glycoproteins composing the mucus with immunoglobulin-like proteins (IGLP) harbored on their capsids have been shown to drastically reduce bacterial colonization of the epithelium. These transient interactions are not directly responsible for the phage accumulation but rather result in a subdiffusive motion of bacteriophages that increases the frequency of phage–host encounters when bacterial densities are low. BAM thus promotes the replication of lytic phages at mucosal surfaces and allows preventing entry of pathogens into the organism by killing bacteria approaching the epithelial cells by viral lysis. BAM may also promote lysogenic conversion of bacteria by temperate phages at these sites. Temperate phages carry functional genes whose expression increases the fitness of infected bacterial cells. Among known adaptive functions found in healthy human virome, one could cite phage superinfection protection, multi-stress resistance and polysaccharide and carbohydrate metabolism genes. By promoting the adaptation and the spread of infected hosts, lysogenic conversion provides to the virus widespread multiplication when the conditions change, leading to the shift of viral replication strategy from lysogeny to lysis. The impact of lysogeny on the bacterial population regulation is thought to be fundamental, and the fact that temperate phages dominate human viromes and are stable over time within individuals suggest that lysogeny plays a major role in the stability and maintenance of the microbiome. Last, phage sequences have also been found in other body compartments that have long been considered as sterile, such as organs and fluids. Several routes for phages entry into the human body have been proposed such as a passage in favor of permeability at cell junctions in inflammatory gut epithelium. But recently, epithelial cells have been shown to be able to translocate phages from their apical to their basal pole, through a way involving the Golgi apparatus, in the absence of bacterial endotoxins that could alter epithelium permeability. The frequency of such transcytosis event is low ($\sim 0.1\%$) but would be sufficient to transport around 31 billion phages per day across the brain-blood barrier, allowing their continuous dissemination all over the human body. Thus, lytic phages would play a systemic role in immunity, protecting all the organs against pathogenic or opportunistic bacteria that could cross the mucosal barrier.

Beside this large majority of phages, each healthy individual harbors, in addition to integrated chromosomal viruses, at least ten permanent chronic systemic viral infections that drive continuous activation of the immune system. These resident viruses include members of the *Herpesviridae*, *Polyomaviridae*, *Anelloviridae*, *Adenoviridae*, *Papillomaviridae*, *Genomoviridae* and *Circoviridae* families (Fig. 2). While some are recognized human pathogens, many others have no known association with human pathology and could even provide benefit to the human host either by viral interference or cross-immunity. For example, it has been hypothesized that ubiquitous human β -papillomavirus may persist on human skin due to its potential to promote skin healing whereas murine norovirus compensates for the absence of intestinal bacteria in germ-free mice and protects against intestinal injury and inflammatory lesions during superinfection with bacterial pathogens. Other murine models have shown that herpesvirus infections may improve the outcome of secondary infection by priming the immune system for protection against bacteria and other viruses. The large prevalence and particularly high genetic diversity observed among members of the *Anelloviridae*, *Papillomaviridae*, *Genomoviridae* or *Circoviridae* families suggest that they may act as human health promoters, by priming the immune system and providing cross-protection against pathogenic strains as established for commensal bacteria. In contrast, viral infection can promote immunosuppression that facilitates secondary infection as it is the case for the depletion of CD4⁺ T cells by HIV whereas the chronic inflammation state maintained by viral infection may increase the risk of inflammatory response due to allergens, of secondary infection or carcinogenesis, as shown for certain members of *Papillomaviridae*, *Herpesviridae* and *Polyomaviridae* families.

Viral interactions with humans are complex and several eukaryotic viruses have established persistent interactions with their host that go beyond simple parasitism. The physiological role of most of these viruses in humans has yet to be defined and the fine balance between adverse or beneficial effects of these interactions probably depends on the virus itself (*e.g.*, viral genotype, replication mode, host range, abundance), the host (*e.g.*, genetic background, age, immune system) and its environment (*e.g.*, geographic location, demographic distribution, animal proximity).

Conclusion

The recent advances in next-generation sequencing over the past decade, have led to the discovery that viruses are an important component of the microbial communities that colonize every ecological niche of the human body. The study of the human virome is an emerging research field and our understanding of how these viruses interact with each other, with the other microbes and their host genetics and immune systems is still fragmented. The next ten years will certainly pave the way for the development of new techniques and integrative approaches that will allow drawing a more precise picture of the human virome and deciphering its role in shaping health and disease.

This is an update of F.A. Murphy, Epidemiology of Human and Animal Viral Diseases, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00390-3.

Glossary

Airborne transmission Transmission via small aerosolized droplets emitted from infected persons from environmental sources.

Case-control study An epidemiological study in which the risk factors of humans or animals with a disease are compared with those without the disease.

Cohort study Attempt to identify the cause of a disease by comparing exposed and nonexposed (control) populations in terms of outcome.

Common source transmission Pertains to contamination of food and water supplies.

Digital epidemiology the use of online data sources to study the determinants, dynamics, and distribution of diseases in populations.

Direct contact transmission Involves actual physical contact between an infected subject and a susceptible subject (e.g. touching, kissing, biting, sexual activity).

Droplet transmission Transmission via large droplets typically traveling a few meters, emitted from infected persons during coughing or sneezing or from environmental sources.

Epidemic (Outbreak) Increase in disease incidence above what is expected in a particular place during a particular time period.

Epidemiology The study of the determinants, dynamics, and distribution of diseases in populations.

Fomite An inanimate object that may be contaminated with virus and become the vehicle for transmission.

Herd immunity The immune status of a population that affects viral transmission rates. Often used in describing the elimination of a virus from a population when there are too few susceptible hosts remaining to sustain a transmission chain.

Horizontal transmission The transfer of infectious virus from one human or animal to another by any means other than vertical transmission.

Iatrogenic transmission Transmission via health care procedures, materials, and workers (e.g., physicians, nurses, dentists, veterinarians).

Incidence risk (or attack rate) A measure of the occurrence of infection or disease in a population over time – it refers to the proportion of a population contracting a particular disease during a specified period.

Mathematical model (epidemiological) A means to convey quantitative information about a host-virus interaction, such as an epidemic or an emerging disease episode, by the construction of a set of predictive mathematical algorithms.

Nosocomial transmission Pertains to infections acquired while a patient, human or animal, is in hospital.

Prevalence The ratio, at a particular point in time, of the number of cases currently present in the population divided by the number of subjects in the population at risk; it is a snapshot of the occurrence of infection or disease at a given time.

Species jumping (or host range extension) Referring to a virus that derives from an ancient reservoir life cycle in animals, but has subsequently established a new life cycle in humans or a different animal species and no longer uses, the original animal reservoir.

Transmission The process by which a pathogen is shed from one host and infects the next.

Vector-borne transmission Involves the bites of arthropod vectors (e.g., mosquitoes, ticks, sandflies).

Vertical or transplacental transmission Transmission of virus from mother to fetus prior to or during parturition, either across the placenta, when the fetus passes through the birth canal, or via colostrum and milk.

Zoonosis Disease which is naturally transmitted to humans from an ongoing reservoir life cycle in animals or arthropods, without the permanent establishment of a new life cycle in humans.

Introduction

Viral disease epidemiology is the study of the determinants, dynamics, and distribution of viral diseases in populations. The risk of infection or disease in a population is determined by characteristics of the pathogen, the host and the environment, as well as behavioral, societal, environmental, and ecological factors that affect virus transmission from one host to another. Epidemiology attempts to meld these factors into a unified whole. The depiction of the interaction of factors favoring the emergence of a viral disease (Fig. 1), called “the convergence model”, is taken from the US Institute of Medicine study, Microbial Threats to Health, Emergence, Detection and Response (National Academy Press, 2003). At the center is a box representing the convergence of factors leading to “the black box”, reflecting the reality that many unknown interactions are important virologically and epidemiologically. Complementing the convergence model, improvements in our understanding of host susceptibility and propensity to transmit viral disease has led to the concept of the “exposome”, the totality of human environmental exposures from conception

Fig. 1 The Convergence Model. Factors contributing to the emergence of viral diseases. At the center is a box representing the convergence of factors leading to the emergence of a viral disease. The black center represents unknown interactions, “the black box”. Reproduced from Smolinski, M.S., Hamburg, M.A., Lederburg, J., (Eds.), 2003. *Microbial Threats to Health, Emergence, Detection and Response*, Fig. 1 p. 3. Washington, DC: National Academies Press. onwards, complementing the genome. The combination of internal and external factors influence the susceptibility of individuals to be infected and transmit viral disease, and in turn of viruses to spread in human populations (Fig. 2).

The foundations of epidemiology predate the microbiological and virological sciences, starting with Hippocrates, the Greek physician and father of medicine, who in the fourth century BC made important epidemiologic observations on infectious

diseases. John Snow is called the father of modern epidemiology because he developed excellent quantitative methods while studying the source of a cholera outbreak at the Broad Street pump in London in 1849. Snow was followed by William Farr, who in the 1870s advanced the use of vital statistics and clarified many of the principles of risk assessment and retrospective and prospective studies. Their vision is reflected in the fast-changing science of epidemiology which is now supported by increased availability and quantity of health and non health data ("big data"), advances in data processing in the form of Artificial intelligence, machine learning and natural language processing, sophisticated statistical methods, and very sensitive and specific diagnostic systems. Improvements in our understanding of the dynamics of disease transmission has placed epidemiology in the center of a complex multidisciplinary network that includes public health, biostatistics, data science, microbiology as well as sociology, anthropology and psychology. Epidemiology in the 21st century is therefore firmly collaborative and sits within a multidisciplinary ecosystem that includes medicine and biology as well as social and computer sciences.

Factors Influencing the Spread of Viral Diseases

Perpetuation of Viruses in Nature

Perpetuation of a virus in nature depends upon the maintenance of serial infections, that is, a chain of transmission; Viruses survive only if they are able to be transmitted from one host to another, whether of the same or another species. Transmission cycles require virus entry into the body, replication, and shedding with subsequent spread to one or several hosts. The potential for the spread of a virus in a population is measure by the basic reproductive number (R_0) defined as the average number of cases directly generated by one case in a population where all individuals are susceptible to infection. A virus will continue to spread in a population (at a speed determined by the R_0) until it runs out of susceptible individuals or control measures that stop or reduce transmission are implemented. The occurrence of clinical disease is neither required nor necessarily advantageous for viruses from a species survival perspective.

Virus Entry

Portals of virus entry into the body include the skin, respiratory tract, intestinal tract, oropharynx, urogenital tract, and conjunctiva. In some cases, viruses use a particular portal of entry because of particular environmental or host-behavior factors and in other cases because of specific viral ligands and host-cell receptors. In many cases, disruption of normal host-defense mechanisms leads to entry that might otherwise be thwarted; for example, papillomaviruses may enter the deep layers of the skin via abrasions, acid-labile coronaviruses may enter the intestine protected by the buffering capacity of milk, and influenza viruses may enter the lower respiratory tract because a drug has dampened ciliary action of the respiratory epithelium.

Virus Shedding

The exit of virus from an infected host is just as important as entry in maintaining its transmission cycle. All portals used by viruses to gain entry are used for exit. The important elements in virus shedding are virus yield (from the standpoint of the virus, the more shedding the better) and timeliness of yield (again, the earlier the shedding the better). Viruses that cause persistent infections often employ remarkable means to avoid host inflammatory and immune responses so as to continue shedding. For example, the epidemiologically important shedding of herpes simplex viruses 1 and 2 that perpetuates the viruses in populations requires recrudescence of persistent ganglionic infection, centrifugal viral genomic transit to peripheral nerve endings, and productive infection of mucosal epithelium, all in the face of established host immunity.

Modes of Virus Transmission

Virus transmission within a species may be "horizontal" or "vertical". The vast majority of transmission is horizontal, that is, between individuals within the population at risk. Modes of horizontal transmission of viruses can be through direct contact, fomites (inert objects that can carry viruses like surfaces, clothes, utensils etc.), airborne transmission, droplet transmission, vector-borne, iatrogenic, and nosocomial. In addition to transmission between individuals, outbreaks of viral disease may occur through a common contaminated source such as food or water. Vertical transmission occurs between the mother and her fetus or newborn. Some viruses are transmitted in nature via several modes, others exclusively via one mode (see [Table 1](#)).

'Direct contact transmission' involves actual physical contact between an infected subject and a susceptible subject (e.g., kissing for the Epstein-Barr virus, the cause of mononucleosis; biting for rabies; sexual activity (genito-genital, anogenital, oro-genital) for herpes).

Indirect contact transmission occurs via "fomites", such as shared eating utensils, improperly sterilized surgical equipment, or improperly sterilized non-disposable syringes and needles.

"Common source transmission" pertains to contamination of food and water supplies (e.g., norovirus diarrhea).

"Airborne transmission" typically results in respiratory infections (and less typically in intestinal infections), Airborne transmission occurs via very small droplet nuclei (aerosols) emitted from infected persons during coughing, sneezing, singing or talking loudly (e.g., influenza, COVID-19) or from environmental sources.

Table 1 Examples of human and animal virus transmission patterns

<i>Infectious agent/disease</i>	<i>Mode of transmission</i>	<i>Portal of entry</i>
Influenza virus/influenza	Contact/direct/indirect via droplets and droplet nuclei	Respiratory tract
Rhinoviruses/common cold	Contact/direct/indirect via droplets and droplet nuclei and fomites	Respiratory tract
Rubella virus/congenital rubella	Contact/direct/indirect via droplets and droplet nuclei	Respiratory tract
Rotaviruses/diarrhea	Vertical/congenital	Transplacental
Poliovirus/poliomyelitis	Contact/direct/indirect via fomites	Intestinal tract (oral)
Norovirus/diarrhea	Contact/direct/indirect via fomites	Intestinal tract (oral)
Hepatitis A virus/hepatitis	Common vehicle/fecal contamination of water	Intestinal tract (oral)
Variant Creutzfeldt–Jakob disease prion/prion disease (spongiform encephalopathy)	Common vehicle/fecal contamination of food/Contact/direct (sexual)	Intestinal tract (oral)
Herpes simplex virus/genital herpes	Common vehicle/bovine spongiform encephalopathy prion contamination of beef or beef products	Intestinal tract (oral)
Human immunodeficiency virus 1/acquired immunodeficiency syndrome (AIDS)	Contact/direct (sexual)	Genital tract
Rabies virus/rabies	Contact/direct (sexual), contact/direct (blood)	Genital tract, bloodstream, transplacental, at birth and via breast feeding
Russian spring summer encephalitis virus/encephalitis	Vertical/congenital	Skin (bite wound)
Dengue viruses/dengue	Zoonotic/contact/direct (saliva)	Skin (tick bite)
Sin Nombre and related viruses	Zoonotic/arthropod-borne	Skin (mosquito bite)
Lassa virus	Zoonotic/contact/direct (rodent urine, saliva and feces)	Respiratory tract
Ebola and Marburg viruses	Zoonotic/contact/direct (rodent urine, saliva and feces)	Respiratory tract and intestinal tract (oral)
Leukemia viruses/leukemias (proven only in animals)	Zoonotic/reservoir host unknown; secondary cases contact/direct/nosocomial and iatrogenic	Index cases unknown, likely respiratory tract or skin and mucous membranes; secondary cases, contact and iatrogenic (injection)
	Vertical/germ-line	Transmitted as genetic trait

Droplet transmission occurs via large droplets ($> 10 \mu\text{m}$ in diameter) that settle quickly. Droplet nuclei can evaporate forming dry particles ($< 5 \mu\text{m}$ in diameter) which remain suspended in the air for extended periods. Droplets may travel only short distances (a few meters) while droplet nuclei may travel over much longer distances.

“Vector-borne transmission” involves an arthropod vector (e.g., mosquitoes, ticks, and sandflies) acquiring the pathogen when biting an infected person and transmitting the pathogen when biting someone else.

“Iatrogenic transmission” involves health care procedures, materials, and workers (e.g., physicians, nurses, dentists, and veterinarians).

“Nosocomial transmission” pertains to infections acquired while a patient, human or animal, is in hospital.

“Vertical or transplacental transmission” occurs from mother to fetus prior to or during parturition. Certain retroviruses are vertically transmitted in animals via the integration of viral DNA directly into the DNA of the germline of the fertilized egg. Other viruses are transmitted to the fetus across the placenta; yet others are transmitted when the fetus passes through the birth canal. Another vertical transmission route is via colostrum and milk. Vertical transmission of a virus may or may not be associated with “congenital disease” (i.e., disease that is present at birth) which may be lethal (and the cause of abortion or stillbirth) or the cause of congenital abnormalities. The herpesviruses, especially cytomegaloviruses, and rubella virus cause important congenital diseases in humans, and pestiviruses, such as bovine viral diarrhea virus, in animals. Viruses acquired vertically can lead to chronic illness later in life, e.g., hepatitis B virus and HIV.

Influence of the Clinical Status of the Host

It is possible for an individual to be infected but present no symptoms (asymptomatic infection) or symptoms so mild that the individual does not identify as ill (subclinical infection). Infected individuals who are asymptomatic or subclinical may however still transmit the disease. This presents a challenge when trying to identify contacts of cases in order to break chains of

transmission, even with the help of laboratory diagnostics. Persistent infections, whether or not they are associated with episodes of clinical disease, also play an important role in the perpetuation of many viruses in nature. For example, prolonged virus shedding can reintroduce virus into a population of susceptibles all of which have been born since the last clinically apparent episode of infection. This is important in the survival of rubella virus in some isolated populations. Sometimes the persistence of infection, the production of disease, and the transmission of virus are dissociated; for example, togavirus and arenavirus infections may have little adverse effect on their reservoir hosts (arthropods, birds, and rodents), but transmission may be very efficient. On the other hand, the persistence of infection in the central nervous system, as with measles virus in subacute sclerosing panencephalitis (SSPE), is of no epidemiological significance, since no infectious virus is shed from this site.

Influence of Virulence of the Virus

The virulence of the infecting virus may directly affect the probability of its transmission, with both extremes providing a disadvantage from a survival perspective. The classic example of this is rabbit myxomatosis. In Australia, mosquito-borne transmission of myxoma virus was found to be most effective when infected rabbits maintained highly infectious skin lesions for several days before death. Highly virulent strains of the virus were found to kill rabbits so quickly that transmission did not occur, and naturally attenuated strains were found to produce minimal lesions that healed quickly and did not permit transmission. In human populations viruses with a very high case fatality rate and a high probability of transmission only when cases are very unwell (such as Ebola or Middle East Respiratory syndrome, MERS) have less potential for global spread than viruses that result in mild or asymptomatic cases and where transmission occurs where symptoms are mild or absent (such as sexually transmitted herpesvirus for example).

Influence of Host Population Immunity

With most viruses, endemic or epidemic transmission leads to increasing levels of immunity in the host population until population immunity is high enough to slow down and eventually interrupt further transmission- the proportion of the population that needs to be immune in order to stop viral transmission is called the herd immunity threshold. It is always below 100% and its exact value varies between viruses according to how transmissible they are (measured by the R_0). The “herd immunity” effect is countered in some cases by viral antigenic variation that causes viruses to evade immunity in previously infected individuals. For example, influenza viruses undergo genetic variations such that persons immune to previously circulating virus strains are susceptible to new strains. Assessing these genetic changes is an important objective of laboratory-based influenza surveillance programs, which in turn are the basis for decisions on the formulation of each year's influenza vaccine.

Influence of Population Size

Long-term survival of a virus requires that it be continuously transmitted from one host to another. In general, for rapidly and efficiently transmitted viruses such as many respiratory viruses, local survival of the virus requires that the susceptible host population be very large. A virus may disappear from a population because it exhausts its potential supply of susceptible hosts as they acquire immunity to reinfection with the same virus. Depending on duration of immunity and the pattern of virus shedding, the “critical population size” varies considerably with different viruses and with different host species. The most precise data on the importance of population size in acute nonpersistent infections come from studies of measles. Persistence of measles virus in a population depends upon a continuous supply of susceptible children. Analyses of the incidence of measles in large cities and in island communities have shown that a population of about half a million persons is needed to ensure a large enough annual input of new susceptible hosts, by birth or immigration, to maintain measles virus in the population. Because infection depends on respiratory transmission, the duration of epidemics of measles is correlated inversely with population density. If a population is dispersed over a large area, the rate of spread is reduced and the epidemic may last longer, so that the number of susceptible persons needed to maintain transmission chains is reduced. On the other hand, in such a situation a break in the transmission chain is much more likely. When a large proportion of the population is initially susceptible, the intensity of the epidemic builds up very quickly and attack rates are almost 100% (“virgin-soil epidemic”). On the other hand, when measles vaccination programs achieve over 95% coverage, the virus disappears almost completely from the population.

Influence of Zoonotic Transmission Cycles

Because most viruses are host-restricted, most viral infections are maintained in nature within populations of the same or related species. However, there are a number of viruses that may have multiple hosts and spread naturally between several different species of vertebrate host, for example, rabies and eastern equine encephalitis viruses. The term “zoonosis” is used to describe multiple-host infections that are transmissible from animals to man. Approximately 70% of emerging infections are zoonoses. Recent example of zoonotic infections that have led to outbreaks or pandemics include Ebola, MERS and COVID-19. Once viruses jump the species barrier, they may cause an outbreak and disappear, or establish themselves in human populations and become endemic.

Influence of Arthropod Transmission Cycles

Many viral zoonoses are caused by arboviruses. Arboviruses have two classes of hosts, vertebrate and invertebrate. Over 500 arboviruses are known, of which about 100 cause disease in humans and 40 in domestic animals; some of these are transmitted by ticks, some by mosquitoes, and yet others by phlebotomine flies (sandflies) or *Culicoides* spp. (midges). Arthropod transmission may be “mechanical”, where the arthropod acts as a “flying pin”, or more commonly, “biological”, involving replication of the virus in the arthropod vector. The arthropod vector acquires virus by feeding on the blood of a viremic person or animal. Replication of the ingested virus, initially in the arthropod's gut, and its spread to the salivary glands takes several days; the interval varies with different viruses and is influenced by ambient temperature. Virions in the salivary secretions of the vector are injected into human or animal hosts during subsequent blood meals. Most arboviruses have localized natural habitats in which specific receptive arthropod and vertebrate hosts are involved in the viral life cycle. Vertebrate reservoir hosts are usually wild mammals or birds; humans are rarely involved in primary transmission cycles, although the exceptions to this generalization are important (e.g., Venezuelan equine encephalitis, yellow fever, and dengue viruses). Humans are in most cases infected incidentally, for example, by the geographic extension of a reservoir vertebrate host and/or a vector arthropod. Ecological changes produced by human activities disturb natural arbovirus life cycles and have been incriminated in the geographic spread or increased prevalence of arbovirus diseases.

Assessment of Disease Occurrence and Outcome

By introducing quantitative measurements of disease trends, epidemiology has come to have a major role in improving our understanding of the overall nature of disease and in alerting and directing disease control activities. Epidemiology is also effective in (1) clarifying the role of particular viruses and viral variants as the cause of disease, (2) clarifying the interaction of viruses with environmental determinants of disease, (3) determining factors affecting host susceptibility, (4) unraveling modes of transmission, (5) evaluating the effectiveness of control measures and (6) field testing of vaccines and antiviral drugs.

At its core, epidemiology concerns itself with describing the occurrence of disease in populations in time (when disease occurs), place (where it occurs) and person (the characteristics of cases). With regards to viral disease, quantifying disease implies either calculating the occurrence of new cases in a population within a specified time period (interchangeably called Incidence, incidence risk, attack rate or cumulative incidence) or the proportion of the population infected at a point in time or over a time period (respectively point and period prevalence). Although of these measures are risks (probabilities), they are sometimes incorrectly referred to as rates. Incidence rate is a separate concept in epidemiology, mainly used in cohort studies (see below) where the denominator is no longer the population but the person time at risk, i.e., the sum of the time-at-risk of infection that each individual in the population contributes. The term “case-fatality rate” (technically a risk or probability) is used to indicate the percentage of subjects with a particular disease that die from the disease. In order to improve understanding of the burden of disease, the measurements (incidence, prevalence, case-fatality) can be calculated and presented stratified by attributes of interest such as age, sex, genetic constitution, immune status, pregnancy, nutritional status, and various behavioral and medical care and patient management parameters. Understanding disparities in health outcomes using measures of disease occurrence stratified by attributes of interest is becoming increasingly important as reducing inequalities in health becomes an explicit objective in global health policy related to infectious diseases.

A viral disease is characterized as “endemic” when there are multiple or continuous chains of transmission resulting in continuous occurrence of disease in a population over a period of time. “Epidemics” or “Outbreaks” are peaks in disease incidence that exceed the endemic baseline or expected rate of disease. A “pandemic” is an epidemic that spreads to more than one region of the globe.

Epidemiological Studies

The description of an epidemiological situation should include the dimensions of time, place and person. A proper description of an outbreak of disease or an epidemic must include the parameters of “person (or subjects in the case of animals), place, and time”. Such descriptive information is a necessary first step in describing the occurrence, distribution, and course of disease, enabling to assess the level of threat, and anticipated action response to the initial recognition of a cluster of cases of disease. In many instances, robust descriptive epidemiology is sufficient to provide the data and evidence required to guide the response to a viral threat. When it is not, a range of analytical approaches can be used to better understand the source of an outbreak and inform the implementation of a control strategy.

Case-control studies and cohort studies

These observational study designs are often used in infectious disease epidemiology to identify associations between an exposure of interest and an outcome. Case-control studies are always retrospective and compare two groups of individuals in terms of exposure: those who have developed the outcome of interest (cases) and those who have not (controls). Case control studies are relatively cheap and quick to run and are particularly well suited to investigate rare outcomes, or when the population of interest is not easily identifiable. One of the key challenges in case control studies is the recruitment of controls that are representative of the

Fig. 3 An example of the use of time series in epidemiology: Weekly all age GP consultations for Influenza like illness in England, 2016–2020 (Source: Surveillance of influenza and other respiratory viruses in the UK Winter 2019–2020 Public Health England).

population of interest in order to avoid bias. Incidence cannot be calculated in case-control studies, which uses odds instead. Odds are the ratio of those developing an outcome (or having an exposure) to those who don't. Typically a case control study measure the ratio of the odds of exposure among cases and controls. Cohort studies compare individuals exposed and not exposed to an exposure of interest in terms of outcome of interest. Cohort studies can be either retrospective (when both exposure and outcome have already occurred) or prospective (when the outcome of interest has not yet occurred). Retrospective cohort studies are commonly used to investigate foodborne outbreak for example where the population is closed and well defined, such as during a wedding or on a cruise ship. Prospective cohort studies are long and expensive to run but provide powerful evidence of association between exposure and outcome. A classic example is the British Doctors study, which followed over 34,000 doctors in total between 1951 and 2001 and established an association between smoking (the exposure) and lung cancer (the outcome).

Time series analysis

These are observational studies widely used in the epidemiology of viral diseases, and in particular in disease surveillance. The two key roles of such an approach are (1) to follow and (2) describe trends of disease overtime establishing seasonality or cyclical patterns spreading over several years (Fig. 3). Examples include establishing and monitoring the seasonality of influenza activity, and characterizing the 2–3 yearly peaks in measles incidence in the absence of vaccine and the lengthening of the cycle as vaccine coverage increases. The second common use of time series is the detection of outbreaks or the beginning of seasonal activity of a particular viral disease through the use of exceedance thresholds. Retrospective time series data provides a baseline, and complex statistical algorithms can detect departure from this baseline, indicating the emergence of an outbreak or the beginning of the season of a viral disease. This approach is commonly used to detect the onset of the influenza or norovirus for example, triggering public health actions such as vaccination and infection control measures in healthcare settings and the community.

Qualitative studies

In recent years the role of quantitative epidemiology to understand the spread and determinants of viral disease has been gradually complemented by qualitative approaches to understanding the epidemiology of viral diseases. While quantitative studies focus on describing the extent of the spread disease and associated risk factors in populations and their subgroups, qualitative approaches help understanding why specific populations are affected by the exposure, the outcome or both. An optimal understanding of the epidemiological of viral disease and the generation of evidence to inform public health action therefore requires a combination of both quantitative and qualitative approaches to understand the spread of viral diseases and its barriers and enablers.

Molecular Epidemiology

The term “molecular epidemiology” is used to denote the use of any of a large number of molecular biological methods in support of epidemiological investigations. The combination of molecular techniques with epidemiology now routinely provides previously unavailable information relevant to the control of infectious diseases such as the ability to ascertain the geographical origin of a viral strain or the ability to link cases in an outbreak investigation with homologous viral sequences even in the absence of an epidemiological link. For example, with herpesviruses, restriction endonuclease mapping has provided a means of identification of unique viral genotypes – in an epidemiologic study recognized as the first based upon viral molecular characterization, the source of herpes simplex virus 1 causing disease in a hospital newborn nursery was traced to one persistently infected nurse rather than any of several other possible shedders. With rotaviruses and bluetongue viruses, polyacrylamide gel electrophoresis of the

segmented viral RNA has been used epidemiologically, for example, to unravel outbreaks involving multiple viral variants. Panels of monoclonal antibodies have been used to distinguish virus variants for epidemiologic purposes; they have been particularly useful in elucidating host-range and geographic variants of rabies virus. Today, partial sequencing has become the most commonly used molecular epidemiologic methodology; partial sequencing of poliovirus isolates recovered from patients indicates whether they are wild type (even local or introduced wild type), attenuated vaccine type, or a vaccine type that has reacquired neurovirulence during human passage. Partial sequencing of foot-and-mouth disease viruses can offer the same kind of geographic information of virus movement as has proved so useful in polio control and eradication programs, but because of political sensitivities in some countries a robust international reference laboratory system has not been established that could provide the same kind of practical disease control information as has been the case with polio. Whole genome sequencing (WGS) is becoming more commonplace and decreases in cost and increases in speed means that WGS is now used as part of routine surveillance activities for many viruses in many countries, enabling unprecedented abilities to map and track the spread of viruses in human and animal populations. Thus, with many human and animal viruses the use of molecular epidemiological techniques are flourishing and expanding, and for some diseases such as influenza have become part of a global surveillance activities. There are many more viral diseases, especially animal diseases, in need of this kind of development.

Seroepidemiologic Studies

Seroepidemiology is useful in public health and animal health investigations and in research to determine the prevalence or incidence of particular infections, to estimate population immunity (either through natural infection or vaccination) in a population or sub groups of a population, and to assess past exposure when a virus is newly identified. Seroepidemiological studies generally aim to detect either immunoglobulin M (IgM), indicating recent infection, or IgG, indicating infection in the past. When paired serum specimens are obtained from individuals several weeks apart, IgG can also be used to detect new infections if IgG antibodies are absent from the first specimen and appear in the second, or if antibody titers rise between the first and second sample. Correlation of serologic tests with clinical observations makes it possible to determine the ratio of clinical to subclinical infections and therefore to determine the proportion of asymptomatic cases. In the COVID-19 pandemic that emerged in 2019, this approach has been essential to identify the existence of asymptomatic carriers and to determine their role in the spread of the pandemic.

Digital Epidemiology

In the past two decades the volume and speed of online data available has increased exponentially. Data from online news sites, news-aggregation services, social networks, web searches, and crowdsourced data from volunteers among others – sometimes referred to as big data- , have been increasingly used to describe the epidemiology of viral diseases and have gradually moved away from experimental research to integrate the formal surveillance landscape. Data-aggregation systems such as the World Health Organization's Epidemic Intelligence from open sources (EIOS) uses advanced analytics such as natural language processing and machine learning to process large quantities of data and provide insights that complement traditional sources of epidemiological data such as laboratory and clinical data. The principal added value of digital epidemiology data is that it can detect the emergence or trends in disease without relying on healthcare seeking behavior. It can therefore describe the epidemiology of diseases for which healthcare is not typically sought, for example acute gastro intestinal illness or acute respiratory infections. It can also detect the emergence of viral threats before they are detected by surveillance systems embedded in healthcare. Several of these systems for examples have claimed to report the emergence of COVID-19 before any official statement from the World health Organization.

Sentinel Studies

Because of advanced diagnostic/serologic methods, sentinel studies can yield many valuable data in timely fashion about impending disease risks. For example, sentinel chicken flocks are set out for the early detection of the presence of arboviruses such as West Nile virus in the United States. These flocks are bled and tested weekly for the presence of virus or antiviral antibody; they provide an early warning of the levels of virus amplification that occur before epidemics.

Vaccine Trials

The immunogenicity, potency, safety, and efficacy of vaccines are first studied in laboratory animals, followed by small-scale closed trials on humans focusing on safety and immunogenicity, and finally in large-scale open trials focusing on efficacy. Such studies use randomized control trials to estimate the efficacy of vaccines. In most cases, there is no alternative way to evaluate new vaccines, and the design of trials has now been developed so that they yield maximum information with minimum risk and acceptable cost. Because trial size is limited by cost and logistical barriers observational studies are required post vaccine implementation to monitor the coverage, safety, effectiveness and impact of vaccines.

Table 2 Criteria for disease causation: A unified concept appropriate for viruses as causative agents of disease, based on the Henle–Koch postulates, and modified by A. S. Evans

1. Prevalence of the disease is significantly higher in subjects exposed to the putative virus than in those not so exposed.
2. Incidence of the disease is significantly higher in subjects exposed to the putative virus than in those not so exposed (prospective studies).
3. Evidence of exposure to the putative virus is present more commonly in subjects with the disease than in those without the disease.
4. Temporally, the onset of disease follows exposure to the putative virus, always following an incubation period.
5. A regular pattern of clinical signs follows exposure to the putative virus, presenting a graded response, often from mild to severe.
6. A measurable host-immune response, such as an antibody response and/or a cell-mediated response, follows exposure to the putative virus. In those individuals lacking prior experience, the response appears regularly, and in those individuals with prior experience, the response is anamnestic.
7. Experimental reproduction of the disease follows deliberate exposure of animals to the putative virus, but nonexposed control animals remain disease free. Deliberate exposure may be in the laboratory or in the field, as with sentinel animals.
8. Elimination of the putative virus and/or its vector decreases the incidence of the disease.
9. Prevention or modification of infection, via immunization or drugs, decreases the incidence of the disease.
10. “The whole thing should make biologic and epidemiologic-sense.”

Mathematical Modeling

From the time of William Farr, who studied epidemic disease problems in the 1870s, mathematicians have been interested in “epidemic curves”, secular trends in the incidence of infectious diseases, and forecasting how the spread of a disease may evolve. Advanced computational power has enabled increasingly complex modeling of the spread of a disease, with an increasing number of parameters being taken into account. Despite the availability of computational power, high profiles models attempting to predict the long term evolution of outbreaks of Ebola (2014–16) or COVID19 (2019–2020) have been consistently wrong and despite the aspiration to predict how outbreaks evolve on the long run, forecasting beyond a few weeks remains very difficult. Models are however an important tool to understand how diseases spread in population in the present, and to assess the likelihood of future scenarios. Mathematical models are also the key decision-making tools to inform the introduction of new vaccines in population as they estimate impact and cost effectiveness.

Data Sharing, Data Privacy and Ethics

As the volume and velocity of data increase, the possibilities of more granular insight about the epidemiology of viral diseases, data linkage and innovative approaches to analytics such as machine learning and natural language processing have vastly increased. Yet these approaches are only as good as the data they rely on. Many datasets remain inaccessible due to privacy and security concerns, and quality is variable due to a lack of standardization and completeness. A global consensus to share quality data in a proportionate, ethical and privacy-preserving manner, where it can improve the health of population is still lacking. Successful control of infectious diseases benefits individuals and communities globally and can be considered a global public good and data is a critical tool that helps achieve this. Governments should therefore improve availability and accessibility of their epidemiological data in order to maximize the generation of evidence to inform control of infectious diseases.

Proof of Causation

One of the landmarks in the history of infectious diseases was the development of the Henle-Koch postulates which established the evidence required to prove a causal relationship between a particular infectious agent and a particular disease. These simple postulates were originally drawn up for bacteria, but were revised in 1937 by Rivers and again in 1982 by Evans in attempts to accommodate the special problem of proving disease causation by viruses (Table 2). With a similar purpose, Austin Bradford Hill established a series a criteria for causation in 1965 (Table 3). While the limit of such criteria remain a debate among epidemiologists, using a set of criteria to determine causality remains a relevant approach since statistical approaches are focused on testing association (rather than causation) between exposure and outcome. In many cases, virologists have had to rely on indirect evidence, “guilt by association”, with associations based on epidemiologic data and patterns of serologic positivity in populations. Today, many aspects of epidemiologic investigation play roles, especially in trying to distinguish an etiological, rather than coincidental or opportunistic relationship between a virus and a given disease. The availability and combination of epidemiological evidence combined with molecular techniques can greatly help with determining the likelihood of causation between exposure and outcome where a statistical association is found (Table 3).

For example, early in the investigation of human acquired immunodeficiency syndrome (AIDS), before its etiology was established, many kinds of viruses were being isolated from patients and many candidate etiologic agents were being advanced. Prediction that the etiologic agent would turn out to be a member of the family *Retroviridae* was based upon years of veterinary research on animal retroviruses and animal retroviral diseases. This prediction was based upon recognition of common biologic and pathogenetic characteristics of AIDS and animal retroviral diseases. This prediction guided many of the early experiments to find the etiologic agent of AIDS; later, after human immunodeficiency virus (HIV1) was discovered, its morphological similarity to equine infectious anemia virus, a prototypic member of the genus *Lentivirus*, family *Retroviridae*, was the key to unraveling

Table 3 Bradford Hill criteria for causation

1. **Strength** (effect size): A small association does not mean that there is not a causal effect, though the larger the association, the more likely that it is causal.
2. **Consistency** (reproducibility): Consistent findings observed by different persons in different places with different samples strengthens the likelihood of an effect.
3. **Specificity**: Causation is likely if there is a very specific population at a specific site and disease with no other likely explanation. The more specific an association between a factor and an effect is, the bigger the probability of a causal relationship.
4. **Temporality**: The effect has to occur after the cause (and if there is an expected delay between the cause and expected effect, then the effect must occur after that delay).
5. **Biological gradient** (dose-response relationship): Greater exposure should generally lead to greater incidence of the effect. However, in some cases, the mere presence of the factor can trigger the effect. In other cases, an inverse proportion is observed: greater exposure leads to lower incidence.^[1]
6. **Plausibility**: A plausible mechanism between cause and effect is helpful (but Hill noted that knowledge of the mechanism is limited by current knowledge).
7. **Coherence**: Coherence between epidemiological and laboratory findings increases the likelihood of an effect. However, Hill noted that "... lack of such [laboratory] evidence cannot nullify the epidemiological effect on associations".
8. **Experiment**: "Occasionally it is possible to appeal to experimental evidence".
9. **Analogy**: The use of analogies or similarities between the observed association and any other associations.

confusion over the fact that the human virus killed host lymphocytes rather than transforming them as typical oncogenic retroviruses would do. Ever since, this essence of comparative medicine has been guiding HIV/AIDS research in many areas, including drug design, diagnostics, and vaccine development. HIV/AIDS epidemiologic research has often been intertwined with research on the several simian immunodeficiency viruses (SIVs).

Conclusion: Implications for Disease Prevention

Knowledge of the epidemiology and modes of transmission of infectious diseases is critical to the development and implementation of prevention and control strategies. Data on incidence, prevalence, and mortality contribute directly to the establishment of priorities for prevention and control programs while knowledge of viral characteristics and modes of transmission are used in deciding prevention and control strategies including vaccine development and delivery, environmental improvements, enhancement of nutritional status, improvement in personal hygiene, and behavioral changes. Epidemiology has become part of a wide multidisciplinary network of disciplines that include laboratory, data and social sciences in order to achieve this objective.

Nomenclature

BCE Before the common era
HBV Hepatitis B virus
HCMV Human cytomegalovirus
HCV Hepatitis C virus
HIV Human immunodeficiency virus
HPV Human papilloma virus
HSV Herpes simplex virus
IAV (IBV, ICV) Influenza A (B, C) virus

MERS Middle East respiratory syndrome
NNRTI Non-nucleoside reverse transcriptase inhibitor
NRTI Nucleoside reverse transcriptase (RT) inhibitor
RSV Respiratory syncytial virus
SARS-CoV Severe acute respiratory syndrome coronavirus
SBV Schmallenberg virus
VZV Varicella zoster virus
WHO World Health Organization
WNV West Nile virus

Glossary

Endemic Infection is constantly/normally present in a geographic area.
Epidemic Rapid spread of infection in a large number of people.
Outbreak Greater number of cases of disease than would normally be expected in a defined population, geographical area or season.
Pandemic An epidemic involving a large proportion of the world population.

Reassortment The process of swapping whole gene segments between two viruses with segmented genomes during replication when a cell is infected by more than one virus strain.
Recombination The process of swapping sections of genome between two viruses during replication when a cell is infected by more than one virus strain.
Virulence Harm a pathogen (virus) does to its host.
Zoonosis A disease that can be transmitted from veterinary species to humans.

Introduction

Emergent viruses include viruses that were not previously identified (emerging) or had either not occurred in a species before or had occurred previously but were limited geographically (re-emerging). The potential for emergent viruses to have a devastating impact on human populations is not a novel phenomenon. In the 1500s, smallpox was introduced into the Americas, resulting in an estimated 10–15 million deaths and the downfall of the Aztec civilization. Nonetheless, even after controlling for confounding factors such as increased awareness and improved surveillance, it is estimated that the worldwide annual occurrence of viral outbreaks has increased substantially in the past 40 years. The 21st century has witnessed the emergence of viral hemorrhagic fevers such as Ebola and Lassa, arthropod-borne virus (arbovirus) infections such as Zika and chikungunya and respiratory infections such as the SARS (severe acute respiratory syndrome) (Addendum added during preparation for publication: This article was written shortly before the emergence of SARS-CoV-2. It therefore refers to SARS-CoV-1 as ‘SARS’) and MERS (Middle East respiratory syndrome) coronaviruses (CoV), to name just a few. Despite improvements in prevention, early detection, control and treatment, emergent viruses remain one of the main causes of human deaths globally and can also have a dramatic impact on livestock species. Viral emergence is typically perceived as a cause of epidemics in which viruses spread quickly in a naïve population. However, not all viruses will adapt to the new host. In general, as the number of susceptible individuals in a population decreases, the epidemic will die out, but as long as the source or reservoir for the virus is still around, there is always a risk that the disease could return.

Although viral zoonoses account for the majority of emerging infectious diseases in the human population, the biological and epidemiological barriers to interspecies transmission are high. Five stages have been proposed to represent the transition from a pathogen that infects only veterinary species (stage 1) to a human-only pathogen (stage 5; Fig. 1). In stage 2, only primary human infection occurs with no onward transmission – examples include Nipah, rabies and West Nile viruses. In stage 3, there are pathogens such as Ebola virus that undergo a few cycles of secondary transmission so that occasional human outbreaks occur. Stages 2 and 3 equate to “spillover infection”; an infection that results in a dead-end infection with no onward transmission or a stuttering chain of limited transmission in the new host. Stage 4 includes viruses that have a natural (sylvatic) cycle of primary transmission from the non-human host but can also cause larger outbreaks with secondary human transmission. The relative importance of primary and secondary transmission can vary. For example, with yellow fever virus, sylvatic transmission is more important than human-to-human spread, while for human-adapted influenza A virus (IAV) there is sustained human transmission.

Fig. 1 The stages of transition of a zoonotic virus from infection of a veterinary species only (stage 1) to becoming a human-only pathogen (stage 5).

Factors in Interspecies Transmission

Viral emergence is often a result of a host shift, which is a relatively rare event and will usually only reach stage 2 due to lack of adaptation of the virus to the novel host. If a virus does not cause severe disease in a novel species, the majority of interspecies transmission events will go unnoticed. There are multiple factors influencing the occurrence of interspecies transmission (or “host jumps”).

Epidemiological or Ecological Barriers

Sustained contact between reservoir hosts (often bats, rodents or birds) and other species increases the likelihood of the emergence of a virus adapted to infect and replicate in a new host. Most of the human-only (stage 5) infectious diseases in temperate zones are thought to have arisen in the Old World (Africa, Asia and Europe), often acquired from domesticated animals. For example, measles is thought to have originated from rinderpest virus of cattle, which has now been eradicated. The most common domesticated animals, including cattle and other livestock species (goats, pigs and sheep) and cats and dogs were domesticated between 8000 and 13,000 BCE, with poultry and equids domesticated slightly more recently (3500–6000 BCE). As a consequence, most novel interspecies transmissions now occur from wildlife species, although these may involve domesticated animals as intermediate hosts, for example pigs act as an intermediate host for the transmission of influenza A and Nipah viruses. Shifts in the epidemiology and ecology of infectious diseases play a significant role in the increasing occurrence of viral emergence (see factors in increasing emergence of viral diseases). There has also been speculation that elimination of a virus from a species might leave a vacant ecological niche that could be filled by a related virus. For example, since rinderpest virus was eradicated from cattle by vaccination, there has been an upsurge of another member of the same virus family, peste des petits ruminants (PPRV), possibly due to the lack of cross-reactive immunity previously provided by rinderpest virus.

Host–Pathogen Interactions

More closely-related species tend to be more susceptible to viruses crossing species barriers because they are more likely to share similar receptors recognized by the virus or have similar innate immune response mechanisms that the virus is already adapted to circumvent.

Viral Factors

Receptor specificity

Receptor specificity is usually the first barrier encountered by a virus during infection. Influenza A virus (IAV) provides a classic example of the role played by receptor specificity in viral emergence. The viral surface protein responsible for entry into host cells is the hemagglutinin (HA). Notwithstanding the recent identification of novel IAV in bats, wild aquatic ducks, particularly in the family *Anatidae*, are regarded as the main reservoir host of IAV. In these hosts, the HA recognizes sialic acids with an $\alpha 2,3$ -linkage to

Fig. 2 The α 2,3 or α 2,6 glycosidic linkage between sialic acid and galactose on cell-surface glycoproteins.

Table 1 Summary of classification of (re-)emergent zoonotic viruses described in this text (International Committee on Taxonomy of Viruses Virus Taxonomy: 2018b Release)

Family-viridae	Genus	Species	Genome
Arena ~	<i>Mammarenavirus</i>	Lassa virus	(-) ssRNA - segmented
Corona ~	<i>Betacoronavirus</i>	Severe acute respiratory syndrome-related coronavirus	(+) ssRNA
Filo ~	<i>Ebolavirus</i>	Zaire Ebolavirus	(-) ssRNA
Flavi ~	<i>Flavivirus</i>	Dengue virus	(+) ssRNA
		Zika virus	
Hanta ~	<i>Orthohantavirus</i>	Hantaan virus	(-) ssRNA - segmented
Orthomyxo ~	<i>Alphainfluenzavirus</i>	Influenza A virus	(-) ssRNA - segmented
Paramyxo ~	<i>Henipavirus</i>	Hendra henipavirus	(-) ssRNA
		Nipah henipavirus	
Peribunya ~	<i>Orthobunyavirus</i>	Schmallenberg virus	(-) ssRNA - segmented
Phenui ~	<i>Phlebovirus</i>	Rift Valley fever phlebovirus	(-) ssRNA - segmented
Reo ~	<i>Orbivirus</i>	Bluetongue virus	dsRNA - segmented
Retro ~ (<i>Orthoretrovirinae</i>)	<i>Lentivirus</i>	Human immunodeficiency virus	(+) ssRNA - RNA reverse transcribing

a galactose (Fig. 2), which are expressed in abundance on both respiratory and gastrointestinal epithelial cells in ducks. Sialic acids with an α 2,3-linkage also predominate in the equine upper respiratory tract; therefore, IAV are believed to have become established in horses as a result of direct transmission from the avian reservoir. In contrast, the sialic acids on cells of the human upper respiratory tract predominantly have an α 2,6-linkage, limiting the likelihood of direct transmission of avian influenza viruses to people. However, the 1918 influenza pandemic appears to have involved direct transmission of an avian IAV that adapted to recognize receptors with α 2,6-linkage.

Ability to adapt

Many of the (re-)emerging viruses have an RNA genome (Table 1). In DNA replication, proofreading enzymes remove misincorporated nucleotides from newly synthesized DNA. This does not occur in RNA replication which, combined with the high rates of replication in RNA viruses, results in a much greater capacity for rapid evolution and hence adaptation to changing environments and new hosts. Furthermore, several of the viral families associated with (re-)emerging disease have segmented RNA genomes. A major consequence of this genome structure is that reassortment can occur, in which genome segments are swapped during replication. When a host cell is infected at the same time with distinct variants, this can result in a virus that combines properties that were previously unique to each parent, which may have a neutral effect or be disadvantageous, but may confer a fitness advantage on the new novel virus. The three most recent pandemics of human IAV involved reassortment. The 1957 pandemic strain was a reassortant of a human H1N1 virus with three gene segments (HA, NA and PB1) from an avian H2N2 virus. The 1968 pandemic strain was a reassortant of the H2N2 human virus in which the HA and PB1 genome segments were from an H3 avian virus. Finally, the 2009 pandemic H1N1 virus appears to have originated from at least three parental strains (avian H1N1, swine H1N1 and human H3N2) through a series of reassortment events in pigs.

Recombination is another larger scale mechanism of genetic variation that can occur in viruses with non-segmented RNA or DNA genomes. The frequency of recombination varies greatly between viruses – it is less common in negative-stranded RNA viruses, but frequent in retroviruses. Recombination, like reassortment, can result in new genome combinations with a fitness advantage, including more efficient replication in a new host. Coronaviruses have the largest single-stranded, positive-sense RNA genome currently known and it is thought to be as a consequence of this that they uniquely encode RNA processing and editing

enzymes that increase the fidelity of replication. However, they have a particularly high rate of homologous recombination (a result of template switching where the corresponding sequence is exchanged between co-infecting viruses). It is thought that recombination contributes to emergence of novel coronaviruses such as turkey coronavirus and SARS-CoV.

Some emerging viruses, such as West Nile virus (WNV) only cause “dead-end” infections in incidental hosts such as equids and humans because there is insufficient viremia for onward transmission by the mosquito vector. Arthropod-borne viruses (arboviruses) such as WNV may be less able to adapt rapidly to new hosts, as changes that are beneficial to replication in the novel host may be detrimental to replication in the insect host.

Virulence

Viruses are often particularly virulent in a new host. It is generally believed that long-term co-evolution results in viruses that are less pathogenic to their natural or reservoir host, either due to tolerance on the part of the host and/or adaptation of the virus to an optimal level of virulence to maximize transmission. A classic example of viral adaptation was observed when myxoma virus, which causes mild disease in its natural host (American rabbits in the genus *Sylvilagus*), was introduced into Australia to control European rabbits (*Oryctolagus cuniculus*). Initially, fatality was close to 100%, but within a few years, the virus became attenuated. The attenuated virus strains have higher rates of transmission due to the host surviving for longer, providing more opportunity for transmission to occur. High levels of virulence in a new host are more likely due to an inappropriate immune response than high levels of virus replication.

In addition to viruses often being particularly virulent in a new host, variation in the ability of a virus to cross species barriers may also be related to changes in its virulence before transmission. This may be illustrated by the interspecies transmission of an equine-adapted IAV to dogs. This was associated with a more virulent strain of the equine virus that caused more frequent and prolonged coughing, which in turn could increase transmissibility of the virus.

Factors in Increasing Emergence of Viral Diseases

There are numerous factors associated with the apparent increase in emergence of viral diseases, most of which have a human element and many of which are inter-related. These include increasing population densities, encroachment on wilderness, dispersal of vectors and pathogens through trade, transport, and migration, and climate change. Growth of the human population has led to increasing population densities and an increase in intensive farming. Intensification of farming can result in high rates of contact between individuals, which may also be more susceptible to infection due to stress, resulting in more opportunities for virus transmission leading to adaptation. On the other hand, backyard farming is often associated with housing different species together and more opportunity for contact with wild animals, increasing the risk of interspecies transmission. A more certain factor in increasing risk of interspecies transmission resulting from the growing population is human encroachment into wilderness habitats bringing them and domesticated species into closer contact with reservoir hosts including monkeys and bats.

Dispersal of vectors and pathogens through trade, transport, and migration has been a factor in the spread of viruses to new regions for centuries. Global distribution of *Aedes aegypti*, the mosquito that transmits dengue, chikungunya, Zika, Mayaro and yellow fever viruses, began with spread from Africa to the Americas associated with the slave trade between the 15th and 19th centuries. During the 18th and 19th centuries, it was spread by trading with Asia with further spread by troop movements after the second-world war. Since the 1980s, the role in dispersal of mosquitoes of worldwide trading of used tires, which when piled in the open can collect small puddles of water provide a mosquito breeding habitat, has been recognized. Historical trade routes connected European countries with Asian and African countries and North America. However, new air routes between countries in sub-Saharan Africa and the Caribbean and Central America could underpin the spread of viruses such as Zika and chikungunya. Whereas conditions are only likely to be favorable for exotic mosquito species to survive in Europe (at least for a short time) if they arrive in summer, conditions are more suitable in the Caribbean and Central America all year round. In the 21st century, viral diseases can be rapidly translocated from one side of the world to the next as billions of people fly between countries annually. The implications of this for dissemination of viral diseases were dramatically illustrated during the emergence of severe SARS in 2002–2003. The virus, which is transmitted in droplets generated by sneezing or coughing, spread to 25 other countries within a few months of its emergence in China with evidence for person-to-person transmission occurring during four international flights. Initially, public health authorities worldwide were ill-prepared for containing international spread of SARS, but no further cases of in-flight transmission were documented after the World Health Organization (WHO) introduced recommendations for screening measures at airports.

Some viruses that were previously controlled by vaccination have re-emerged for a variety of reasons, such as breakdown in public health systems because of civil strife. Others, such as measles, are re-emerging because of vaccine hesitancy.

Prevention and Control of Emerging Viruses

Appropriate measures to prevent and control emerging viruses are highly dependent on the individual situation. For example, what is known about the mode of transmission (either directly or by inference from related viruses) and whether diagnostic tests and vaccines are already available dictate the possible courses of action. Where vaccines are not yet available, or to augment vaccines, prevention of disease focuses on avoiding exposure to infection. Thus may involve education of the public and healthcare

Fig. 3 World Health Organization list of priority diseases for the WHO R&D Blueprint.

workers to avoid behaviors that lead to disease transmission. For example, avoidance of contact with rats, which transmit Lassa fever virus, in Nigeria. More drastic measures may be taken to control outbreaks of an emerging virus in livestock, including culling infected animals (“stamping out”). It is generally easier to impose movement restrictions for livestock than people. More extreme and costly control measures can only be achieved with substantial investment from governments and non-governmental organizations. Increasingly, prevention of spread of emerging viruses requires international co-ordination – a role chiefly undertaken by the WHO and the World Organization for Animal Health (OIE).

In 2015, the WHO first published a priority list of eight emerging diseases likely to cause major epidemics for which current prevention and control measures are inadequate – all viral diseases. In 2017, the WHO refined the process for selecting these priority diseases, assembling a panel of experts to undertake a Delphi process to first create a shortlist then to rank the viruses on the shortlist using a multi-criteria decision analysis and finally to further refine the list with a second Delphi round (Fig. 3). The final list of 10 diseases proposed in 2017 formed the WHO “blueprint” of diseases requiring prioritized research and development efforts. The current list (after a review in 2018) contains Crimean-Congo hemorrhagic fever (CCHF), Ebola virus disease and Marburg virus disease, Lassa fever, Middle East respiratory syndrome coronavirus (MERS-CoV) and Severe Acute Respiratory Syndrome (SARS), Nipah and henipaviral diseases, Rift Valley fever (RVF), Zika and “disease X”. Inclusion of disease X, a pathogen not yet known to cause human disease, exemplifies the need for platforms for developing interventions that can be readily (and rapidly) adapted to deal with future epidemics caused by unforeseen pathogens.

There has been extensive investment of resources in efforts to predict the next pandemic, but increasingly it is recognized that it is critical to ensure enhanced ability to identify, through surveillance, and rapidly and appropriately respond to an emerging virus threat. However, as more data are acquired from emerging disease outbreaks, there is greater scope to develop risk-based models that can inform authorities where to focus surveillance efforts and adaptive mathematical models that can be used to help make appropriate decisions during the course of an outbreak.

Diagnosis

Diagnosis of viral disease by detection of virus was traditionally very resource-intensive with virus isolation requiring cell culture, inoculation of embryonated hen’s eggs or intracerebral inoculation of suckling mice or, for non-cultivable viruses, the use of electron microscopy. Attempts to isolate virus remain important for comprehensive viral characterization, and development and

testing of vaccines and antiviral drugs. However, more rapid diagnostic techniques are now available such as ELISA for detection of viral proteins and molecular methods such as PCR. The emergence of Schmallenberg virus (SBV), a midge-borne virus affecting ruminants that was hitherto unheard of, highlighted how technological advances have accelerated our capacity to identify emerging viruses. In the summer and autumn of 2011, the etiologic agent of a disease causing fever, decreased milk yield and diarrhea in cattle in Germany and Holland could not be identified using existing diagnostic tests. Metagenomic analysis was performed on samples taken in October 2011 and viral sequences most similar to viruses in the Orthobunyavirus genus of the family *Bunyaviridae* (according to the classification at the time, now the *Peribunyaviridae*), were identified, and SBV was subsequently isolated. This was the first example of next-generation sequencing being used to identify an emerging virus. Furthermore, the first commercial ELISA to detect antibodies to SBV entered the market in April 2012. The company was able to rapidly develop the indirect ELISA following the same principles used for a kit already developed for Rift Valley fever virus. Nonetheless accurate diagnosis of some groups of viruses continues to pose a challenge. For example, clinical diagnosis of important human flavivirus infections such as Zika, Japanese encephalitis, and dengue viruses is difficult because of the overlap in their geographical distribution (defined by their mosquito hosts) and their similar clinical disease spectrum. Transient viremia means that laboratory diagnosis by PCR-based methods frequently returns a false negative result and serological diagnosis is complicated by high levels of cross-reactivity of antibodies. Therefore, there is a need to improve the availability of reliable and cost-effective diagnostic tests that can be deployed wherever required to enable effective control and prevention measures to be implemented before an emerging virus has the opportunity to develop into an epidemic.

Treatment

Particularly when an emergent virus has not been identified previously, or did not cause sufficient human disease to warrant investment in vaccine development, antiviral drugs may be important in the control of disease. The first antiviral drug to be approved for human use in 1963 was Idoxuridine, a 5-substituted 2'-deoxyuridine analog active against herpes simplex virus. Since then, antiviral drugs with various modes of action (see [Table 2](#) for summary) have been approved for use against several human viral diseases. In the absence of an effective vaccine, vast amounts have been invested in development of anti-viral drugs for human immunodeficiency virus (HIV) and, more recently, hepatitis C virus (HCV). The development of antiviral drugs is a lengthy and costly process, but broad-acting antiviral drugs such as ribavirin may be effective against emerging viruses. In addition, interferons, immunostimulators, oligonucleotides, and antimetabolic inhibitors can be used against various human viruses.

In general, antiviral drugs are not widely used to treat livestock animals due to their expense, but there may also be a desire to restrict antiviral drugs to treatment of severe human cases to limit the opportunity for development of widespread drug-resistant variants. For example, it is thought that injudicious use of the IAV antiviral amantadine in poultry in Egypt led to a high proportion of resistance to this drug among H5N1 avian influenza virus isolates and veterinary pharmaceuticals containing antiviral compounds are now banned in Egypt. There are also concerns that the active metabolite of the IAV antiviral oseltamivir is not removed by conventional sewage treatment and can be found in river water at concentrations that might be sufficiently high to drive selection of drug-resistant variants of IAV in ducks.

Table 2 Summary of licensed antiviral drugs

Drug group	Approved use	Mechanism (s) of drug action
5-substituted 2'-deoxyuridine analogs	HSV, VZV	Inhibit viral DNA polymerase
Nucleoside analogs	HBV	Inhibit viral DNA polymerase
Pyrophosphate analogs	HCMV, (acyclovir resistant HSV)	Inhibit viral DNA polymerase
NRTIs	HIV, HBV	Target HIV RT to competitively inhibit DNA synthesis
NNRTIs	HIV-1	Bind directly to HIV RT and inhibits DNA synthesis
Protease inhibitors	HIV, HCV genotype 1	Block active site of protease to prevent cleavage of viral precursor proteins
Integrase inhibitors	HIV	Target HIV integrase to inhibit the integration of viral DNA into human chromosomes
Entry inhibitors	RSV, HSV, HIV, VZV	Specifically block binding of viral surface proteins to entry receptors
Acyclic guanosine analogs	HSV, VZV, HCMV	Inhibit viral DNA polymerase activity
Acyclic nucleoside phosphonate analogs	HCMV, HIV, HBV	Inhibit the activity of HCMV DNA polymerase
Direct-acting antivirals (DAAs) against HCV	HCV	Four classes used in combination that inhibit NS3/4A protease, inhibit NS5A, and nucleoside analogs or non-nucleoside analogs that inhibit NS5B polymerase
Direct-acting antivirals (DAAs) against influenza viruses	IAV (IBV and ICV)	Three classes that target matrix protein 2 to inhibit viral uncoating, neuraminidase to inhibit virus release from host cells or activity of RNA polymerase
Ribavirin	IAV, HCV, RSV, some hemorrhagic fever viruses	Target viral RNA polymerase to inhibit mRNA synthesis

Key: HBV, hepatitis B virus; HCMV, human cytomegalovirus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papilloma virus; HSV, herpes simplex virus; IAV (IBV, ICV), influenza A (B, C) virus; NRTI, nucleoside reverse transcriptase (RT) inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; RSV, respiratory syncytial virus; VZV, varicella zoster virus.

Because direct-acting antivirals (DAA) are often associated with the rapid development of antiviral resistance, there is increasing interest in the potential of drugs that target cellular pathways required for viral replication rather than the virus itself. A drawback of this approach is that drugs that target key host cell pathways are more likely to be associated with adverse side-effects than virus-specific drugs. Nonetheless, there are opportunities to “repurpose” drugs that have already been through phase I and II clinical trials, for example as potential cancer therapeutics. Combining *in silico* structure-based screening and high throughput screening assays of the large chemical libraries now available may identify potential compounds for treatment of emerging viruses.

Vaccination

Vaccination is generally considered the most effective method to prevent infectious diseases and strategic vaccination programs were central to the eradication of smallpox and rinderpest, the only two viral diseases to have been eradicated to date. However, development and safety testing of vaccines against novel viruses takes time and financial resources. Furthermore, it may not be apparent in the early stages of an outbreak whether investment in vaccine development will ultimately be profitable. Therefore preparedness for emerging and re-emerging viruses is largely contingent on international organizations such as GAVI, the vaccine alliance founded by the Bill and Melinda Gates Foundation. For example, GAVI funds a continually replenished emergency stockpile of 6 million doses of yellow fever virus (YFV) vaccine. Compassionate use of an investigational vaccine that had not yet undergone the full testing required to be licensed was recently permitted for the control of Ebola.

“Ring vaccination”, in which only those directly exposed or most at risk of infection are vaccinated, is a strategic approach to contain a virus outbreak when, for example, limited doses of vaccine are available. The approach is particularly effective in the control of outbreaks in livestock when used in combination with a diagnostic test that allows a DIVA (differentiation of infected from vaccinated animals) strategy to be employed. This approach was used when equine IAV first emerged in Australia in 2007 by vaccinating with a canarypox-vectored vaccine expressing only the IAV hemagglutinin and screening with an ELISA that detects antibodies to the nucleoprotein, which will only be expressed in infected animals. However, in the case of a novel emerging virus disease of livestock, inactivated virus vaccines are more often the first to be licensed. When there is no capacity to distinguish antibodies that result from vaccination rather than infection, it can be difficult to declare a region free of disease leading to prolonged trade restrictions being imposed.

Control of Mosquito Vectors

The *Aedes aegypti* mosquito has several behavioral features that make it particularly difficult to avoid contact with. It generally lives indoors and near people, moves very quickly and may bite repeatedly, often around the feet and ankles. Because the bite is not particularly painful, it can go unnoticed, and it also feeds during daylight hours, therefore using bed nets is not effective.

Traditional mosquito control programs involving the use of insecticides have had limited long-term success due to the development of resistance. The release of large numbers of radiation-sterilized insects has been successful for the control of several insect species that are agricultural pests, but less so for mosquitoes. “Transgenic” sterile male mosquitoes have been developed. For example, genetically-modified male mosquitoes that are homozygous for a late-acting dominant lethal transgene that is transmitted to the embryo *via* the sperm and leads to death of the zygote. Disadvantages of this method are that it only places a temporary restriction on disease transmission by reducing mosquito numbers, but population levels will return to normal levels when release of sterile insects stops. A novel approach is to release mosquitoes infected with an intracellular bacterium called *Wolbachia*. *Wolbachia* is a genus of gram-negative bacteria that infects many different insect species. Introducing strains from fruit flies into mosquitoes shortens the life span of female mosquitoes, which are responsible for disease transmission, but, importantly, some strains also increase the resistance of mosquitoes to infection with various pathogens. *Wolbachia* is a maternally inherited endosymbiont; therefore, release of *Wolbachia*-infected mosquitoes replaces indigenous mosquito populations with mosquitoes that block pathogen transmission. Early trials of the *Wolbachia* approach have focused on the control of dengue. Dengue is the most significant human arboviral disease with an increasing number of countries at risk for dengue infection. A field trial in an Australian city that involved the release of around 4 million *Wolbachia*-infected *Aedes aegypti* mosquitoes over an area of 66 square kilometers has shown promising results. Further trials are being conducted in Indonesia, where there is a much higher incidence of dengue, and areas where no mosquitoes are released are included. Release of *Wolbachia*-infected mosquitoes in large cities in Brazil and Colombia will also determine whether the strategy is effective in densely-populated areas with high incidence of dengue.

Concluding Remarks

Recent human epidemics caused by Ebola and Zika viruses have fueled increased research efforts and attracted media attention to emerging viruses. With increased globalization, density of populations, climate change and changes in habitat, there is increased risk of interaction within and between species. This provides more opportunities for the emergence of viruses by increased contact and interspecies transmission as well as spread of viruses into geographic regions where they have not been found before. Whilst a major driver of emerging virus disease research is public health concern over zoonotic infections, emerging viral diseases may have devastating effects on veterinary species with consequent impact on security of food production and the survival of wildlife species.

Increasingly, there is also the potential for emerging viruses to affect pet animals, causing welfare issues and distress to owners. This article has focussed exclusively on animal viruses, but emerging plant viruses also pose a serious threat to agricultural production, and similar factors, such as changes in agricultural practices and global transport of plant materials, have led to increased emergence of plant viruses. Understanding the drivers of viral emergence is vital to inform efforts to mitigate against its impact and this requires a one-health approach involving collaboration between the human and animal health and environmental and social fields.

Glossary

Apoptosis A form of programmed cell death.

Apoptotic bodies Remnants of cells which underwent apoptosis.

Complement system A pathogen-triggered cascade of biochemical reactions involving more than 20 soluble and cell-bound proteins. Complement activation results in opsonization, priming of humoral immune responses, and perforation of membranes.

Cytokines Proteins which mediate cell–cell communication related to pathogen defense. Secreted by immune cells or tissue cells.

Innate immunity Physical and chemical barriers, cells, cytokines, and antiviral proteins which exclude, inhibit, or slow down infection with little specificity and without much adaptation or generation of a long-lasting protective memory.

Interferons (IFNs) Cytokines mediating antiviral activity. Distinguished into type I (IFN- α/β), type II (IFN- γ), and type III (IFN- λ). Type I and type III IFNs directly mediate antiviral activity in responding cells, whereas type II IFN is more immunomodulatory.

Interferon-stimulated response element (ISRE)

A promoter element common to all type I IFN-stimulated genes.

Opsonization Tagging of infected cells or pathogens for destruction by phagocytic cells.

Pathogen-associated molecular patterns (PAMPs) Molecular signatures of pathogens used by the innate immune system to distinguish self from non-self. Often highly repetitive patterns.

Pattern recognition receptors (PRRs) Intracellular and extracellular receptors recognizing specific PAMPs.

Phagocytosis Uptake of particles by cells.

Introduction

Viruses attempting to conquer a mammalian body are faced with an impressive array of hurdles. “Innate immunity” in a wider sense comprises all sorts of factors which exclude, inhibit, or slow down infections in a rapid manner but with little specificity and without adaptation or generation of a long-lasting protective memory. Many of these efficient and not at all primitive defenses are evolutionarily old and can be found in all metazoans. For the sake of brevity, however, the discussion in this article is mostly restricted to mammals. RNA interference, the innate immune system of plants and non-vertebrates, is not covered.

Mammalian innate immune defenses against virus infections can be divided into several distinct parts such as mechanical and chemical barriers (not further mentioned here), defensins, complement system, phagocytic/cytolytic cells of the immune system which act in a nonspecific manner, and cytokines.

Defensins

Defensins are small, cysteine-rich cationic, amphipathic peptides with broad activity against bacteria, fungi, and viruses. They are produced by immune cells and skin and mucosal epithelial cells, and are present on epithelia and in body fluids. On top of their constitutive expression levels, defensin genes can be induced by viral infection. Their most common antimicrobial function is the formation of destructive pores in membranes of pathogens including enveloped viruses. Defensins can however also block infection by enveloped and non-enveloped viruses alike by aggregating the particles, blocking receptor binding, inhibiting virus entry, particle uncoating or intracellular trafficking, interfere with essential cell signaling or viral gene expression, or act by other, ill-understood mechanisms. Moreover, besides these direct antiviral activities, defensins were shown to attract immune cells and modulate adaptive immune responses. Since defensins activities are mostly studied in cell culture, it is thought that their immunomodulatory action is currently underestimated.

Complement System

The complement system (which “complements” the adaptive immune system in the defense against pathogens) primes the adaptive immune response and is also directly effective against pathogens. Complement activation is achieved by specific receptors recognizing pathogens or immunocomplexes. Three different pathways are being distinguished which are termed the classical pathway (triggered by antigen–antibody complexes), the mannan-binding lectin pathway (triggered by lectin binding of pathogen surfaces), and the alternative pathway (triggered by complement factor C3b-coated pathogen surfaces). They all activate a cascade of reactions involving more than 20 soluble and cell-bound proteins, thus resulting in a rapid and massive response. The

complement system is able to (1) tag infected cells and pathogens for destruction by phagocytic cells (opsonization), (2) prime humoral immune responses, and (3) perforate membranes of infected cells by the membrane-attack complex. In response, viruses have evolved effective countermeasures such as incorporation of cellular complement-regulatory proteins into particles or expressing specific inhibitors in infected cells.

Cellular Innate Immunity

Macrophages/monocytes, granulocytes, neutrophils, natural killer cells, and dendritic cells belong to the cellular branch of the innate immune system. Monocytes circulate in the bloodstream for several hours before they differentiate into macrophages. These potent phagocytic cells either continue patrolling or they permanently settle in particular tissues (i.e., the Kupffer cells of the liver), being able to rapidly remove viral particles and apoptotic bodies. Activated macrophages also synthesize inflammatory cytokines such as IFN- γ and tumor necrosis factor (TNF)- α , thus triggering an adaptive immune response. Granulocytes are also able to remove viral particles and apoptotic bodies by phagocytosis. They are rapidly attracted to inflammatory sites and enter the tissue by transendothelial migration. Both macrophages and granulocytes cleave the ingested viral proteins into fragments and present them to T lymphocytes. Neutrophils (polymorphonuclear cells) are also phagocytosing pathogens, among other directly acting activities. Their most fascinating ability is however the release of neutrophil extracellular traps (NETs), which are networks of proteins and chromatin that immobilize and inactivate extracellular pathogens. Natural killer (NK) cells are able to recognize infected cells in an antigen-independent manner and destroy them by their cytotoxic activity. Also, they rapidly produce large amounts of IFN- γ to activate the adaptive immune system. NK cells are regulated by a fine balance between stimulatory and inhibitory receptors. One of their prominent features is their ability to destroy cells which lack MHC I molecules on their surface. As many viruses downregulate MHC expression in order to avoid an adaptive immune response, NK surveillance represents an important early warning and attack system against virus infections.

A key connection between the innate and the adaptive immune system is provided by dendritic cells (DCs). These specialized immune cells sample antigen at the site of infection, activate themselves and the surrounding tissue cells by cytokine synthesis, and then migrate to secondary lymphatic organs in order to mobilize T cells against the presented antigen. The differentiation of DCs into efficient antigen-presenting cells (APCs) is achieved by cytokine production which, in turn, is triggered by stimulation of receptors recognizing pathogen-specific molecular patterns (PAMPs). Two main types of DCs are being distinguished: myeloid DCs (mDCs) and plasmacytoid DCs (pDCs). mDCs are an early split-off of the myeloid bone marrow precursors, that is, the stem cells which are also at the root of macrophage/monocyte and granulocyte differentiation, among others. Depending on the location, several subsets of mDCs such as Langerhans cells (residing in epidermis and epithelia) or interstitial cells are being distinguished. pDCs, which are not segregated into subpopulations, are derived from lymphatic precursor cells, that also generate the B and T cells, for example. Both mDCs and pDCs can sense viral infection by several intra- and extracellular PAMP receptors (see below). Depending on the DC type, high levels of interleukins or IFNs are being produced which coin the subsequent immune reaction. pDCs are potent producers of the antiviral type I IFNs.

Antiviral Cytokines: The Type I Interferons

Isaacs and Lindenmann discovered in 1957 that cells which had been in contact with inactivated virus particles secrete a soluble factor which confers cellular resistance to influenza viruses, a phenomenon called “interference”. In the subsequent years, it became more and more clear that the so-called type I IFN (encompassing IFN- β and a set of IFN- α subtypes) system is our primary defense mechanism against viral infections. In fact, humans with genetic defects in the IFN signaling pathway have a bad prognosis as they die at an early age of viral diseases which would otherwise pose little problems. Similarly, knockout mice with a defective type I IFN system quickly succumb to viral pathogens of all sorts although they have an intact adaptive immune system.

In response to virus infection, pDCs are particularly well equipped to synthesize and secrete IFN- α/β , but in principle all nucleated cells are able to do so. In an autocrine and paracrine manner, IFNs trigger a signaling chain leading to the expression of genes for potent antiviral proteins which limit further viral spread. In addition, IFNs initiate, modulate, and enhance the adaptive immune response. The signaling events which culminate in the direct IFN-dependent restriction of virus growth can be divided into three steps, namely (1) transcriptional induction of IFN synthesis, (2) IFN signaling, and (3) antiviral mechanisms.

New Kids in the Gut: The Type III Interferons

Type III IFNs (IFN- λ s), a relatively recent discovery, are distinct antiviral cytokines with many features in common with type I IFNs. IFN- $\lambda 1$, $\lambda 2$, and $\lambda 3$ are induced by virus PAMPs and normally signal through the JAK/STAT cascade, but use a separate receptor. They are able to activate expression of interferon-stimulated genes (ISGs) and have been shown to inhibit replication of viruses. However, whereas all nucleated cells express the receptor for type I IFNs, the type III IFN receptor is limited to epithelial cells on mucosal barriers. IFN- λ s are therefore important for limiting the infection and transmission by respiratory and gastrointestinal viruses. Moreover, while type I IFN signaling activates ISG expression in a fast, strong and transient manner, type III IFN signaling is characterized by a weaker,

Fig. 1 Depending on the virus, ssRNA, dsRNA, 5'ppp-RNA, dsDNA, or combinations thereof represent characteristic by-products of infection (i.e., PAMPs) which are recognized by PRRs to induce production of antiviral IFN- α/β and intracellular factors with antiviral or regulatory function. The viral PAMP signature molecules are recognized in the endosome by TLRs (a), and after entry into the cytoplasm by intracellular PRRs (b).

delayed, but longer-lasting ISG response. Besides the direct antiviral effect mediated by ISGs, IFN- λ s are stimulating adaptive immune responses. Interestingly, type III IFNs are also responsible for the elevated immunogenicity of live attenuated vaccines as compared to inactivated vaccines, since only the former are triggering IFN- λ production. Thus, IFN- λ s are complementing the IFN response by conferring a lasting, local protection at anatomical sites which are most exposed to viral intruders.

Interferon Induction

Nucleic acids are the main PAMPs of viruses, being recognized by a number of pattern recognition receptors (PRRs) to initiate induction of IFN genes (see Fig. 1). Classes of virus-triggered PRRs can be divided into the endosomal toll-like receptors (TLRs) and various intracellular (mostly cytoplasmic) receptors. It is thought that the TLRs can be activated by viral nucleic acids that had been released from virus particles (or endocytosed remnants of infected cells) that were dissolved by the endosomal low pH and/or degradative enzymes. Major PAMPs are double-stranded RNA (dsRNA), single-stranded RNA (ssRNA), 5'-triphosphorylated (ppp) RNAs, and double-stranded DNA (dsDNA). dsRNA and 5'ppp-RNA are underrepresented in uninfected cells, thus predestining them as immunorelevant markers of non-self. In the case of ssRNA and dsDNA, it is thought that unusual locations (e.g., endosome or cytoplasm for DNA), a lack of cell-typical modifications (e.g., methylation), or specific secondary structures are responsible for triggering antiviral responses. Moreover it should be noted that a full-blown infection converts the heterogeneous population of cellular nucleic acids into a pool of largely homogeneous, highly abundant viral RNAs and/or DNAs. Thus, immunogenicity could also be caused by over-representation of uniform RNA or DNA species.

dsRNA is an almost ubiquitous by-product of virus infection that is sensed by a multitude of PRRs. In the endosome it is recognized by the TLR3, and in the cytoplasm by the RNA helicases RIG-I and MDA-5 (collectively termed RIG-I-like receptors, RLRs) and the protein kinase PKR. Substantial amounts of dsRNA are produced by viruses with a positive-strand ssRNA or with a dsRNA genome (e.g., coronaviruses or reoviruses, respectively) during genome transcription and replication. For DNA viruses (e.g., Herpes viruses or poxviruses), it is thought that dsRNAs are formed either by hybridization of read-through transcripts from promoters on opposite DNA strands, or from secondary structures present on particular viral RNAs. Viruses with a negative-strand ssRNA genome (e.g., influenza virus) are unique in that they do not produce substantial amounts of long dsRNA, since their genome and antigenome RNAs are always encapsidated by viral nucleoprotein. In the cytoplasm, their genomes are recognized by RIG-I in a 5'-triphosphate-dependent manner. In addition a short dsRNA region, formed by the annealing of complementary 5' and 3' ends of the RNA genome (the so-called "panhandle"), is essential for RIG-I to be activated.

Viral ssRNAs can be recognized in the endosome by TLR7 and -8.

The third important PAMP, viral dsDNA, is again recognized both by an endosomal receptor, TLR9, and a series of intracellular receptors such as e.g., IFI16, DDX41, RNA polymerase III, and cGAS. dsDNA recognition by RNA polymerase III actually represents a crosstalk between the RNA-PRRs and the DNA-PRRs, since the polymerase transcribes viral DNA into 5'ppp-dsRNA which then activates RIG-I. A similar second messenger principle is realized by cGAS (cGAMP synthase) which produces cyclic di-GMP-AMP (cGAMP) molecules in response to cytoplasmic dsDNA. cGAMP, in turn, activates the adapter protein STING (stimulator of interferon genes) and hence downstream antiviral signaling.

Besides nucleic acids, some viral proteins can provoke a TLR response such as the envelope proteins of respiratory syncytial virus and measles virus by activating TLR4 and TLR2, respectively.

All PRRs are triggering signaling chains (with partial crosstalk and usage of common adapters and kinases) which canonically culminate in activation the IFN regulatory factor (IRF) -3, the general immune-regulatory transcription factor NF- κ B, and the stress-activated transcription factor AP-1. In cooperation, they upregulate IFN gene expression. This leads to a “first wave” of IFN production (IFN- β and IFN- α 4 in mice) which triggers the expression of the transcription factor IRF-7. IRF-7 is a master regulator of IFN gene expression cooperating with IRF-3 for full activity. IRF-7 can be activated in the same way as IRF-3 and is responsible for a positive-feedback loop that initiates the synthesis of several IFN- α subtypes as the ‘second-wave’ IFNs.

While all cells with a nucleus are thought to be equipped with the set of intracellular PRRs, expression of TLRs is more restricted to epithelial and immune cells. mDCs, for example, can sense dsRNA by the classic intracellular RLR pathway and, in addition, by TLR3. pDCs sense the presence of viral ssRNA or dsDNA by TLR7, TLR8, and TLR9 to transcriptionally activate multiple IFN- α genes. This broad and strong IFN induction is due the presence of constitutively expressed IRF-7 in pDCs, which enables them to bypass the dependency on IRF-3 and to directly launch a “second-wave”-like IFN response. IRF-7 is further upregulated in response to IFN and generates a positive-feedback loop for high IFN- α and IFN- β production. Furthermore, TLR7 and TLR9 are retained in the endosomes of pDCs to allow prolonged IFN induction signaling.

Type I IFN Signaling

IFN- β and the multiple IFN- α subspecies activate a common type I IFN receptor (IFNAR) which signals to the nucleus through the so-called JAK-STAT pathway (Fig. 2). The signal transducer and activator of transcription (STAT) proteins are latent cytoplasmic transcription factors which become phosphorylated by the Janus kinases JAK1 and TYK2. Phosphorylated STAT1 and STAT2 recruit a third factor, IRF9, to form a complex known as IFN-stimulated gene factor 3 (ISGF3) which translocates to the nucleus and binds to the IFN-stimulated response element (ISRE) in the promoter region of ISGs.

The collective term “ISGs” implies a common, uniform mode of regulation. In fact, however, there are three different classes of ISGs, first of all those classical ones responding to IFN signaling (STAT dependent), those responding either to IFN signaling or to PRR activation by PAMPs (universal ISGs), and those that exclusively respond to PRR activation (IRF dependent). The latter ones are not ISGs in a proper sense (but often called so), since they are stimulated by infection rather than by IFN. Moreover, for some ISGs regulation can differ between animal species or between cell types, and by far not all ISGs are entirely characterized with respect to the ISG class they belong to.

Direct Antiviral Effects of Type I IFNs

Type I IFNs activate the expression of several hundred STAT dependent ISGs of which only a fraction has been studied in great detail. Well characterized examples with broad antiviral activity are the 2’–5’ OAS/RNaseL system, protein kinase R (PKR), RNA-specific adenosine deaminase 1 (ADAR1), ISG20, IFN-induced tetratricopeptide repeat (IFIT) protein 1, the Mx proteins, viperin, and tetherin. 2’–5’ OAS and PKR are constitutively expressed in normal cells in a latent, inactive form. Basal mRNA levels are upregulated by IFN- α/β and these enzymes need to be activated by viral dsRNA. The 2’–5’ OAS catalyzes the synthesis of short 2’–5’ oligoadenylates that activate

Fig. 2 IFN- α and IFN- β bind to the type I IFN receptor (IFNAR) and activate the expression of numerous ISGs via the JAK/STAT pathway. OAS, ISG20, Mx, ADAR, PKR, Tetherin, Viperin and IFIT1 are examples of proteins with antiviral activity. IRF-7 amplifies the IFN response by upregulating PAMP-dependent expression of several IFN subtypes.

the endoribonuclease RNaseL. RNaseL, an ISG in most species (humans are an exception expressing it constitutively), degrades viral and cellular RNAs. PKR is a serine-threonine kinase that phosphorylates – among other substrates – the α -subunit of the eukaryotic translation initiation factor eIF2 to block translation of cellular and viral mRNAs. PKR also plays a role in virus-induced NF- κ B activation, as described above. ADAR1 catalyzes on viral dsRNAs the deamination of adenosine to inosine. As a result the secondary structure is destabilized due to a change from an AU base pair to the less stable IU base pair, and the accumulating mutations are hampering viral replication. Recent research showed that ADAR1 is important to suppress the formation of dsRNA structures by endogenous Alu retroelements. In ADAR1-deficient animals, endogenous RNAs are not edited, and the arising dsRNAs activate the PRRs MDA5 and PKR, leading to chronic IFN induction, inhibition of mRNA translation, and eventually autoimmunity. ISG20 is on one hand an exonuclease that degrades viral ssRNA, but in the other hand it was recently found to downmodulate translation of non-self mRNAs in an RNase-independent manner. IFIT1 is expressed at extremely high levels after IFN stimulation or PRR signaling and sequesters viral RNA with a 5'ppp end or an unmethylated cap. Mx proteins are enwrapping viral nucleocapsids, thus preventing the viral polymerase from elongation of transcription. Viperin (Radical S-adenosyl methionine domain containing 2, RSAD2) is an enzyme that converts the nucleotide CTP to a chain terminator for viral RNA-dependent RNA polymerases. Tetherin (bone marrow stromal cell antigen 2; BST2) is a transmembrane protein able to restrict the release of enveloped virus particles from the plasma membrane.

The antiviral profiles of the IFN effectors listed above are distinct but often overlapping. Mx proteins, for example, mainly inhibit segmented negative-strand RNA viruses and also Semliki Forest virus, whereas the 2'-5' OAS/RNaseL system appears more important against positive-strand RNA viruses. Moreover, only rarely the presence of one particular IFN effector explains host resistance. Rather, it is the sum of antiviral factors affecting, for example, genome stability, genetic integrity, transcription, and translation that confers the full antiviral power of IFN.

Indirect Antiviral Effects of Type I IFNs

Besides the effector proteins listed above, several ISGs contribute in a more indirect manner to the enhancement of both innate and adaptive immune responses. Virus-sensing (and in part antiviral) PRRs such as TLR3, PKR, RIG-I, and MDA5 are by themselves upregulated in an IFN-dependent manner. Similarly, IRF-7 and STAT1, the key factors of type I IFN and ISG transcription, respectively, are ISGs. The strong positive-feedback loop mediated by the upregulation of these PRRs and transcription factors is counterbalanced by several negative regulators (e.g., LGP2, SOCS, PIAS), which are either ISGs or depend on IFN signaling for their suppressive action.

Type I IFNs can directly enhance clonal expansion and memory formation of CD8⁺ T cells. Also, IFNs promote NK cell-mediated cytotoxicity and trigger the synthesis of other cytokines such as IFN- γ or IL-15 which modulate the adaptive immune response, enhance NK cell proliferation, and support CD8⁺ T-cell memory. Moreover, by upregulating TLRs, MHCs, and costimulatory molecules, IFNs enable APCs (most prominently DCs) to become competent in presenting viral antigens and stimulating the adaptive immune response.

Innate Immunity Memory

Since long, the lack of any type of memory is used as a feature distinguishing innate from adaptive immunity. It became meanwhile clear, however, that IFNs can reprogram cell responses by leaving epigenomic signatures on promoters, mostly by post-translational modifications of histones. This memory-like mechanism can last for weeks, and explains the long-known phenomenon of “priming”, i.e., that a first small shot of IFNs is potentiating the effect of a second IFN treatment. A phenomenon related to priming is “innate immunity training”. Here, prior inflammation or infection enhances a second innate response and inflammation, again via changing epigenomic signatures.

Tonic IFN Levels

Although the classical model outlined above depicts that PRR-triggered upregulation of IFN- β starts from level zero, at least at barrier tissues basal levels of IFN expression are maintained constantly. This “tonic” IFN expression is thought to be a reaction to commensal bacteria, and primes the organism for rapidly reacting to pathogenic invaders.

Viral Counterstrategies

Given the massive direct and indirect antiviral effects of type I IFNs, it comes as no surprise that viruses had evolved efficient countermeasures. In fact, most viruses investigated so far were found to actively inhibit either IFN induction, IFN signaling, antiviral ISG action, or combinations thereof. A common strategy to avoid IFN induction seems to be the targeting of treacherous dsRNA or 5'ppp structures by binding, modifying, or degradation through viral factors, the so-called IFN antagonists. Moreover, many viral features such as encapsidating genomic RNA by nucleoprotein (negative-strand RNA viruses), hiding replication

complexes in intracellular membrane compartments (positive-strand RNA viruses) or multiple protein sheets (dsRNA viruses), as well as replicating in the nucleus (orthomyxoviruses) can be regarded as passive strategies to minimize generation and exposure of PAMPs to PRRs. Active strategies include sequestration or degradation of key factors of antiviral signaling like PRRs, kinases, IRFs, STATs or even RNA polymerase II itself. The bundle of these measures, i.e., the individual anti-IFN profile of a particular virus, can represent a major marker for host range, cell tropism, and virulence. Weak anti-IFN capabilities can render a virus unfit in a given host, whereas strong IFN suppression enables productive replication. Fine-tuning the IFN antagonistic activities may allow the adaption to optimal host-to-host transmission. Depending on the particular transmission mode and host population density, either massive, damaging viremia (like e.g., for arthropod- or aerosol-transmitted pathogens) or lower-level, locally restricted or chronic infection (e.g., herpes, papilloma or hepatitis C viruses) are positively selected for. In the case of the persistent infections, long-term production of IFN can even be beneficial for the virus as it results in an immunosuppression aimed at limiting immunopathology. Thus, the balance and timing of activation versus suppression of the IFN response can determine the outcome of infection, ranging from a straight fending off (host wins by early antiviral IFN action) to acute disease (virus wins by suppressing early IFN action) to chronic viral disease (constant IFN levels maintain infection by suppressing immune responses). In any case, the simple equation: strong IFN antagonism = virulent virus, weak IFN antagonism = harmless virus, should be applied with some caution.

Good Cop–Bad Cop

Given their massive impact on the cellular gene expression profile, it is quite expected that type I IFNs have not only antiviral, but also antiproliferative and immunomodulatory effects. Treatment with IFNs is an established therapy against several viral and malignant diseases such as hepatitis B, hepatitis C, Kaposi's sarcoma, papillomas, multiple sclerosis, and several leukemias and myelomas. However, the strong and systemic effects of IFNs do not come without a price. Administration of IFN can locally produce inflammation, and systemically cause fever, fatigue, malaise, myalgia, and anemia. It is no coincidence that these latter are "flu-like" symptoms, since in many acute infections IFNs play a dominant role. The effects of IFN which are desired and beneficial if restricted to the site of first infection can turn into a life-threatening "cytokine storm" if it becomes systemic. Severe acute respiratory syndrome (SARS) and human infections with H5N1 influenza viruses are examples of such out-of-control innate immune responses. Moreover, long-term and high IFN levels are facilitating persistent infections, as discussed above, and IFN therapy can aggravate autoimmune disorders. Another "dark side" aspect is the so-called interferonopathies. Patients with mutated PRRs or IRFs exhibit type IFN gene expression signatures and are prone to autoimmune diseases. Chronic production of IFNs causes maturation of mDCs, which in turn activate autoreactive T and B cells.

Concluding Remarks

The concept of innate immunity certainly comprises more than the IFN system (see above), but type I and type III IFNs represent a central part. These cytokines not only have direct antiviral effects but also orchestrate the first defense reactions and the subsequent adaptive immune response, thus determining the course of infection. The fact that basically every virus appears to have evolved one or several countermeasures for controlling the IFN response is testament to its importance. In addition, IFNs are not only antiviral, but also effective tumor suppressors. Tumor cells often eliminate the IFN system during the transformation process. The payoff is an increased susceptibility to infection, an Achilles heel which is exploited by the therapeutic concept of oncolytic viruses. Tumor selectivity of such viruses can be even more increased by using IFN-sensitive mutants. The inability of those mutants to fight the IFN response is complemented by the mutations of the tumor cells, thus allowing virus growth. At the same time, these viruses are unable to infect the IFN-competent healthy cells.

Cells had to cope with viruses since the early days in the primordial pond. No wonder innate immune responses are so astonishingly multi-faceted, consisting of a wide array of cells, signaling chains and effector molecules solely dedicated to the elimination of infectious intruders. Viruses are the most abundant biological entities on earth, but most accidental contacts are not even noticed by us. Only those viruses which had evolved tailor-made counterstrategies can break through and establish infection for long enough to be multiplied and transmitted further. The innate immune system may be old, but as long as there are viruses (and tumors), it will never come out of fashion.

Role of the Innate Immune System in the Initiation of the Adaptive Immune Response

Introduction to Barrier Immunity

On a daily basis, we encounter numerous micro-organisms. We are, however, protected from the majority of them by physical and chemical barriers, consisting of epithelial cells of the skin and the mucus layer covering internal mucosal surfaces, which together provide the first line of defense. These surfaces host a microbial ecosystem or microbiome comprising largely bacteria and fungi, which collectively outnumber the cells in the human body and provide a hostile environment for infectious pathogens. The skin and mucous membranes serve not only as a passive physical barrier but also as a site of active immune surveillance, which is provided by diverse immune effector cell populations. Their function is to send the first warning signals upon detection of potential pathogens. Viruses, along with other microbes, gain entry to the body either when the skin barrier is broken or via contact with exposed mucous membranes, such as those of the upper respiratory and gastrointestinal tracts. Because viruses can only replicate by co-opting host nucleic acid and protein synthetic machinery, they have evolved specific mechanisms to attach to and gain entry into their target cells.

Innate Immune Effectors are Poised to Respond to Viruses That Overcome Barrier Protection

The first immune responses to viral infections are mediated by effector cells of the innate immune system. In contrast to adaptive immune responses, they are initiated within hours, are non-specific and are coordinated via signaling pathways that are common to many cell types. The effector populations are mononuclear (macrophages) and polymorphonuclear (neutrophils) phagocytes, innate lymphoid cells, natural killer (NK) cells and dendritic cells. As discussion of each of these in depth is beyond the scope of this article, we highlight the innate cell populations that play a key role in the induction of humoral and cellular immune responses to viruses. Innate immune responses may be associated with local and systemic inflammation, a tightly regulated, physiological process mediated by chemokines and cytokines that leads to increased blood flow, enhanced permeability of the vasculature and recruitment of phagocytic cells to the site of infection. Phagocytosis is an evolutionarily conserved physiological process in which invading pathogens are recognized via cell surface receptors, internalized into a phagosome and subsequently destroyed. While thought to be primarily a defense mechanism against extracellular pathogens, macrophages and neutrophils are capable of eliminating virus-infected cells by phagocytosis. Along with other invading pathogens, they may be tagged with molecules known as opsonins, which serve to enhance the efficiency of the phagocytic process.

Natural killer (NK) cells are a subset of innate lymphoid cells that are typified by the expression of CD56 and absence of CD3. They can be further segregated based on FCγRIIIA (CD16) expression. Their antiviral functions can be broadly categorized as: (1) cytotoxicity, mediated by the release of cytolytic granules, perforin and granzyme, or in some circumstances, the engagement of death receptors on target cells and (2) the secretion of pro-inflammatory cytokines such as interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α). A unique antiviral effector function of NK cells is antibody-dependent cellular cytotoxicity (ADCC), mediated by CD16 by recognition of antibody-decorated ('opsonized') virally infected cells. The secretion of cytolytic granules and cytokines upon activation is immediately triggered by encounter with virus-infected cells and does not depend on prior exposure to antigen. Because of this, NK cell cytotoxicity is tightly regulated by the balance of inhibitory and activating signals that are transduced by killer immunoglobulin (Ig) receptors (KIRs) when they detect loss of major histocompatibility complex (MHC) molecules on the infected cell surface. NK cells also express several other classes of receptor, including C-type lectin receptors that detect stressed cells via MHC homologs (MICA/B). While NK cell responses to viruses are generally non-specific, the concept of NK cell memory, or trained immunity, has been proposed in the light of evidence of a long-lived NK cell subset that shows a rapid response to re-encounter with viruses, which is a feature of adaptive immune responses.

Barrier immunity, early onset inflammatory responses, microbial phagocytosis, and NK cell effector responses may be sufficient to eliminate viral infections. However, viruses have evolved various strategies to evade the innate immune system. Under these circumstances, elimination of the infection requires engagement of the adaptive immune system to provide a highly specific and potent response that can be recalled if necessary, i.e. upon re-exposure to the same or similar pathogens. Dendritic cells (DC) play a central role in priming adaptive immune responses by B and T cells. Originating in the bone marrow, after release into the circulation they migrate to tissues where they continually sample the extracellular environment, particularly at sites of pathogen entry. They capture pathogens by endocytosis, either in their native form, or by engulfing infected cells or apoptotic cell debris. Antigen capture in tandem with danger signals from pathogens causes DC maturation, manifested by upregulation of co-stimulatory molecules and migration to lymphoid tissue, where they encounter and activate naïve T cells. DC are further categorized as myeloid (mDC) and plasmacytoid (pDC). mDC are the most potent antigen-presenting cells (APC) while pDC secrete inflammatory cytokines and type I interferons when activated by detection of viral nucleic acids.

Innate Immune Recognition of Viruses

Immune sensing of viral components is mediated by germline-encoded pattern recognition receptors (PRRs) that recognize broadly conserved pathogen-associated molecular patterns (PAMPs) such as viral DNA, single stranded RNA, 5'-triphosphate-containing RNA, double-stranded RNA and viral proteins. A vast array of PRRs has been described; these can be classified by their cellular location. Cell surface receptors that recognize viral components include C-type lectin receptors and some Toll-like receptors (TLRs), namely TLR 2 and 4. Intracellular receptors include endosomal TLRs (TLR 3, 7, and 9) and cytoplasmic NOD-like receptors (NLRs), RIG-I-like receptors (RLRs) and double-strand DNA sensors (interferon-inducible protein-16 and cyclic GMP-AMP synthase) (Table 1). Ligation of viral components by PRRs activates signaling cascades, resulting in the production of type I and type III interferons (IFNs) and other proinflammatory cytokines and chemokines, which act as a chemoattractant for phagocytic cells. In addition, the expression of co-stimulatory molecules (e.g., CD40 and the B7 family, CD80 and CD86) on these cells is increased. Secreted IFNs bind to receptors on infected and uninfected cells, inducing the expression of numerous IFN-stimulated genes. Type I interferons (IFN- α and IFN- β) encode proteins that induce an antiviral state, for example, enzymes that edit viral RNA and DNA (e.g. adenosine and cytidine deaminases) or directly antagonize viral proteins involved in replication (e.g., The tripartite motif-containing protein (TRIM) family). Type III interferon (IFN- λ) also induces an antiviral state, although this may be more limited due to the restricted expression of IFN- λ receptors.

Crosstalk Between Innate and Adaptive Immune Cells

The process of antigen presentation bridges the innate and adaptive immune systems and is a crucial step in the initiation of the adaptive immune response. Professional APCs, namely mature DC, macrophages and B cells, display processed intracellular protein antigens on the cell surface in the form of peptides bound to of MHC molecules (human leukocyte antigen, HLA, in humans). MHC/peptide complexes are recognized by T cell receptors (TCRs) expressed on CD4+ and CD8+ T cells. MHC molecules are encoded by MHC genes on chromosome 6 and are divided into two major classes, I and II. Structural differences between MHC class I and class II molecules underlie differential preferences in the lengths of peptides that are accommodated in the peptide binding groves of these molecules. MHC class I molecules bind peptides that are 8–11 amino acid (aa) long while MHC class II bind longer peptides between 13 and 25 aa length. MHC class I is expressed on the surface of all nucleated cells while MHC class II expression is restricted to professional APCs. Viral antigens access MHC class I and II molecules via segregated pathways: phagocytosed viruses or viral products enter an exogenous pathway in which they are degraded in endosomes before transport into the endoplasmic reticulum (ER) and loading onto MHC class II molecules; proteins that are generated in the cytosol in infected cells as a result of viral gene transcription enter an endogenous pathway in which they are degraded in the proteasome and transported by cellular chaperones to the ER, where they are loaded onto MHC class I molecules. Peptide-loaded MHC complexes (pMHC) are transported via Golgi apparatus to the surface of the cells for cognate recognition by TCRs.

Exceptions to these rules are: (1) the phenomenon of cross-presentation in professional APCs, whereby phagocytosed virions or viral proteins escape from endosomal compartments into the cytosol and enter the endogenous pathway, leading to presentation by MHC class I; (2) access of cytosolic peptides to MHC class II molecules as a result of autophagy, the process of recycling of organelles and proteins in lysosomes as observed in the presentation of Epstein-Barr virus nuclear antigen (EBNA1) and Influenza matrix protein (MP1) to CD4 T cells.

The importance of antigen presentation in the development of the adaptive immune response to viruses is evident in the primary immunodeficiency syndrome, Bare lymphocyte syndromes I and II, an autosomal recessive genetic disorder where gene defects lead to a lack of expression of MHC class I and II respectively and carriers are known to suffer from multiple persistent viral infections. Furthermore, downregulation of MHC presentation is one of the most well-characterized mechanisms used by viruses to avoid T cell recognition. This is achieved by diverse mechanisms operating at different stages of the processing and presentation pathways described. For example, herpes simplex virus type 1 and cytomegalovirus encode proteins (ICP47, US6 and US3) that interfere with peptide loading in the ER, while human immunodeficiency virus type 1 (HIV-1) Nef diverts MHC class I molecules to the trans-Golgi network and Epstein-Barr virus (EBV) BLZF1 gene represses the transcription of MHC class II transcriptional activator (CIITA).

The Adaptive Immune Response to Viral Infections

Overview

The adaptive or acquired immune response to all pathogens, including viruses, provides protection from infection upon re-exposure to the same or similar micro-organisms. It is mediated by T and B lymphocytes that express antigen-specific cell surface receptors. Key elements of the adaptive immune response are: antigen specificity that results from the selection of TCRs and B cell receptors (BCRs) from a vast repertoire of receptor variants; receptors are generated by gene rearrangements and are selected on the basis of self/non-self-discrimination; responses are honed by a process of maturation in specialized lymphoid organs; after resolution of the infection, a proportion of T cell and B cell clones survive and are able to re-expand rapidly upon re-encounter with cognate antigen, providing immunological memory. In contrast to the innate immune response, the adaptive immune

response evolves over time and therefore does not provide immediate protection against invading pathogens. However, protection is durable and in some cases, lifelong, due to the longevity of a subset of T cell and B cell clones.

T Cell Recognition of Viral Antigens

Lymphoid progenitor cells (thymocytes) develop from hematopoietic stem cells in the bone marrow and migrate to the thymus where they undergo sequential selection steps to ensure that only functional non-autoreactive T cells enter the circulation. Here, thymocytes first begin to express TCRs as a result of random recombination of TCR V(D)J gene segments. TCRs are heterodimeric membrane-bound proteins, comprising a pair of disulfide-linked polypeptide chains. The vast majority of TCRs comprise paired alpha and beta chains ($\alpha\beta$ TCR) while a minority consists of paired gamma and delta chains ($\gamma\delta$ TCR). During the process of TCR generation, thymocytes become committed to either CD4 or CD8 T cell lineage through the expression of CD4 or CD8 co-receptors, which confer distinct specificities for MHC molecules. Positive selection ensures that only thymocytes capable of interacting with MHC molecules survive: those that bind strongly to MHC class II become CD4⁺ T cells while those that bind to MHC class I become CD8⁺ T cells. Positively selected thymocytes that show strong reactivity to self antigens are subsequently deleted, or undergo clonal diversion or receptor editing in a process termed central tolerance. Eventually, single-positive CD4 and CD8 T cells exit the thymus as naïve T cells that circulate between blood and peripheral lymphoid organs, including the lymph nodes and tonsils, which they constantly patrol in order to detect their specific antigens.

The α and β chains of the TCR each consist of an extracellular portion that structurally resembles an Ig antigen-binding fragment, a transmembrane domain and a cytoplasmic tail. The extracellular portion of each chain comprises a variable (V) domain, which binds to the peptide-MHC complex, and a membrane-proximal constant (C) domain. The V regions contain 3 segments of highly variable amino acid sequences, or complementarity-determining regions (CDR), that are generated by random gene rearrangements, as described earlier. The third hypervariable region (CDR3) directly contacts the peptide-MHC complex and has the highest level of diversity, due in part to the random addition of non-germline encoded nucleotides. The $\alpha\beta$ TCR forms part of the TCR complex, together with non-covalently associated signal-transducing molecules, CD3 and the zeta chain, which initiate T cell activation upon recognition of antigen. These signals are amplified by the interactions of the co-receptors, CD4 and CD8, which make contact with the β 2 region of MHC class II and the α 3 region of MHC class I respectively.

T Cell Effectors in the Response to Viral Infections

CD4⁺ T Cells

CD4⁺ T cells were originally known as helper T (Th) cells due to recognition of their essential roles in providing help to cytotoxic T cells and B cells, which were identified in experimental models of viral infections. CD4⁺ T cells are activated upon interaction with professional APCs presenting specific peptides bound to MHC class II and receive signals that drive their differentiation into one of several effector populations with distinct functions. The factors that govern this differentiation program include the quality and dose of antigen, the duration of TCR engagement with the peptide-MHC complex, the co-stimulatory signals provided by the APC, and the cytokines present in the environment during T cell activation. Together, these induce the expression of key transcription factors and signaling transducer and activator of transcription proteins (STATs) that drive commitment to specific Th lineages. There are at least 5 major and well-described CD4⁺ T cell subsets: Th1, Th2, Th17, T follicular helper (Tfh), and regulatory T (Treg) cells. Viral antigens favor Th1 and Tfh differentiation, and Tregs play a crucial role in modulating virus-specific effector responses, therefore, for brevity we have focused on these subsets. Th1 cells in particular have been implicated in the response to virtually all viral infections. While CD4⁺ T cells have long been considered to play an indirect role in the adaptive immune response to viruses, namely, orchestrating the recruitment and effector programs of B cells and CD8⁺ T cells, a subset of cytotoxic CD4⁺ T cells may play a direct role by lysing virally infected cells. Recent evidence has revealed an important role for these cytotoxic CD4⁺ T cells in the response to diverse viruses (discussed below). Finally, it should also be noted that there is plasticity in CD4⁺ T cell differentiation and lineage commitment is not necessarily irreversible (Fig. 1).

T Helper 1 (Th1) Cells

Commitment to this lineage is driven by the secretion of IFN γ and interleukin-12 (IL-12) and the expression of the transcription factor T-bet in activated CD4⁺ T cells. A defining feature of Th1 effector response is the secretion of cytokines IFN- γ , IL-2 and tumor necrosis factor- α (TNF- α). These cytokines are crucial in the CD4⁺ T helper-mediated activation of cytotoxic CD8⁺ T cells, as was demonstrated in early experimental mouse models using lymphocytic choriomeningitis virus (LCMV): infection of CD4-depleted mice resulted in a reduction in cytotoxic CD8⁺ T cell responses. The secretion of IFN- γ and TNF- α was also shown to have direct antiviral effects in the LCMV model and in viral infections such as herpes simplex type 1 (HSV-1) and measles virus (MV).

T Follicular Helper (Tfh) Cells

One of the most well described T helper functions is the provision of help to B cells by Tfh cells, a specialized subset of CD4⁺ T cells, that drive germinal center (GC) formation in lymphoid follicles, antibody isotype (class) switching, the production of

Fig. 1 Subsets of cells within the adaptive immune system. T and B lymphocytes are composed of various cell subsets that differentiate from lineage-naïve cells upon antigen priming. They produce various cytokines and antibodies in response to stimulation. durable, potent and high affinity antibodies and the generation of memory B cells in the GCs. Tfh differentiation involves a multi-step program, initiated by IL-6, IL-12, and IL-23, which upregulate the transcription factor B cell lymphoma protein 6 (Bcl-6), and is followed by increased surface expression of the chemokine, CXCR5, together with IL-21 secretion. This leads to CXCL13-dependent migration of Tfh cells to the GC. Here, encounter with cognate antigens on B cells drives their maturation into GC Tfh cells that coordinate the GC reaction.

Even before the formal characterization of this cell subsets in the 2000s, there was an appreciation for CD4 + T cells help in the generation of potent antibody responses. In the murine vesicular stomatitis virus model, CD4 T cells were shown to be essential for the generation of virus-specific neutralizing antibodies. Furthermore, it was observed that chronic LCMV infection could skew the Th differentiation program towards Tfh cell differentiation. Tfh frequency and/or function was also found to correlate with viral control in LCMV and Zika virus infections. In addition, virus-specific Tfh cells have been detected in patients with acute hepatitis C (HCV) infection and their functional activity correlated with the development of antibodies over time.

Regulatory T Cells (Tregs)

Tregs negatively regulate the immune response to prevent tissue damage caused by uncontrolled inflammation. Natural Tregs (nTreg) are generated in the thymus via recognition of self-peptides and upregulate the transcription factor, Foxp3. Induced Tregs arise in the periphery in response to IL-10-mediated induction of transforming growth factor- β (TGF- β), which may accompany the inflammatory cytokine cascade that is provoked by viral infections. Tregs exert suppression of T cells and other effector cells via multiple mechanisms, including the secretion of cytokines such as IL-10 and TGF- β , metabolic disruption leading to Th cell nutrient deprivation or apoptosis and inhibition of DC maturation. An example of their regulatory function is the attenuation of the T cell-mediated inflammatory response to HSV-1 in the corneal stroma of the eye, that can otherwise lead to blindness. However, Treg-mediated regulation of T effector responses can also hinder viral clearance, as has been observed in cervical dysplastic lesions caused by human papillomavirus (HPV).

Cytotoxic CD4 + T Cells

These non-canonical CD4 + T cells recognize antigens in association with MHC class II, yet display cytolytic activity in a similar manner to CD8 + T cells, either by the release of cytotoxic granules or by engagement of death receptors on infected cells. Although their differentiation from naïve CD4 + T cells is poorly defined, they express CD57 and lectin-like receptors that are more commonly found on NK cells, which suggests that they arise in the context of chronic antigen exposure. A protective role for this cell subset has been described in numerous viral infections including HIV-1, influenza A virus (IAV), hepatitis B (HBV), HCV, cytomegalovirus (CMV), and EBV infections. They may compensate for the loss or exhaustion of cytotoxic CD8 + T cells in chronic infection.

CD8 + Cytotoxic T Cells (CTL)

CD8 + T cells are able to recognize and kill virus-infected cells and to secrete cytokines and chemokines that inhibit viral replication and entry into neighboring cells. Their indispensable role in protection from disease and in the clearance of viral infections was first demonstrated in adoptive transfer and CD8 + T cell depletion experiments in mouse models. Similar to CD4 + T helper cells, CD8 + T cells differentiate into diverse cytotoxic T cell subsets depending on the initial signals they receive from APCs, the antigen load and the cytokine environment. APC-derived IL-12 and IFN- γ are important for the induction of cytolytic proteins, perforin and granzymes. They can be defined as Tc1, Tc2, Tc17, and Tregs in an analogous fashion to Th cells, ie according to their cytokine secretion profile and effector functions. The acquisition of cytolytic capacity is under the control of the transcription factors T-bet, eomesodermin. Blimp-1 is also implicated in efficient killing (Fig. 1).

A population of CD8 T cells that express the chemokine CXCR5, follicular cytotoxic T cells (TFC) have recently been described in chronic viral infections including murine LCMV, simian immunodeficiency virus (SIV), HIV-1 and EBV infections. These CXCR5 + CD8 + T cells are known to migrate to follicles and lyse virus-infected cells. They may also provide 'help' to B cells to generate class-switched antibodies.

Mounting an Effective T Cell-Mediated Immune Response to Viral Infections

T Cell Priming

Naïve T cells that encounter APCs displaying a specific viral peptide can be activated to respond to the infection, provided they receive the appropriate signals. The process of T cell priming by DCs, which encompasses activation, clonal expansion and differentiation, takes between 3 and 7 days. According to the 3-signal paradigm, signal 1 is provided by the interaction of the TCR with the peptide-MHC complex; signal 2 requires the binding of co-stimulatory molecules on the surface of T cells to their respective ligands on APCs, while signal 3 is mediated by APC-derived cytokines that are induced by PRR activation. The interaction of CD28 on T cells and B7 molecules on APCs provides co-stimulatory signals that are crucial for T cell survival and induces the production of IL-2, which drives clonal expansion and effector cell differentiation. The absence of co-stimulation leads to a state of anergy, in which the T cell is refractory to further antigenic stimulation.

As stated earlier, DCs and macrophages are professional APCs that upregulate MHC class II as they mature, enabling peptide presentation to CD4 + T cells. In addition, they express MHC class I and are capable of direct presentation of viral peptides to naïve CD8 + T cells if they become infected by viruses. This has been demonstrated in the context of many viral infections, including vaccinia virus (VACV), murine and human CMV, human lymphotropic virus type 1 (HTLV-1), Dengue virus (DV) and HSV. They are also capable of cross-presentation, which may be important to the effectiveness of the response to IAV, HIV-1, HSV-1, and EBV.

Following activation, T cells undergo clonal expansion of several thousand-fold and, depending in part on the third signal they receive, they differentiate into the specialized subsets previously described, giving rise to virus specific effector T cells that are poised to respond to viral infections and to migrate to the site of infection.

T Cell Help

CD4 + T cells provide help to cytotoxic CD8 + T cells in two principal ways: (1) via the secretion of cytokines such as IL-2 and IL-21, that may promote the survival and lytic capacity of CD8 + T cells and (2) the interaction of DCs with CD4 T cells via CD40-CD40 ligand (CD40L) interactions, which license DCs to prime naïve CD8 + T cells. In addition, CD4 + T cells secrete cytokines and chemokines that attract CD8 + T cells to the site of infection and promote their migration towards DCs. Although CD8 + T cells can be activated directly by DCs, CD4 + T cell help is considered to be essential for optimal CD8 + T cell effector function and for durable memory responses.

The help provided by CD4 + Tfh cells to B cells constitutes several functions, including the provision of signals that promote survival and proliferation, plasma cell differentiation and the induction of AID, which drives somatic hypermutation and Ig class switch recombination. These are primarily mediated by CD40L-CD40 interaction and by the cytokines IL-4 and IL-21. They are also dependent on cell-to-cell contact, which is facilitated by adhesion molecules expressed on Tfh cells. Subpopulations of Tfh cells

influence the development of different antibody subclasses, for example, IFN- γ -producing Tfh1 cells favor the class switching of B cells to the production of the IgG subclass, IgG2a, which has antiviral effects.

Cytotoxicity

The specific killing of virally infected cells by activated CD8 + T cells involves the formation of an immunological synapse (IS), which ensures that neighboring uninfected cells are unharmed. Initial contact between the infected target cell and the effector CD8 + T cell is stabilized by the interaction of adhesion molecules on each cell (intracellular adhesion molecule-1 or ICAM-1 and lymphocyte function-associated antigen-1 or LFA-1, respectively) and is followed by engagement of the TCR with peptide-MHC. This triggers the accumulation of TCR complexes at the point of contact, together with rearrangement of the cytoskeleton and mobilization of perforin and granzymes towards the IS. Perforin forms holes in the target cell membrane, through which lysosomes containing granzymes are delivered. Granzymes induce apoptosis of the target cell by activating caspase-3, which directs the degradation of target cell DNA. After this process is complete, the effector cell detaches from the target and may engage in serial killing of other targets by the same mechanism. The importance of perforin/granzyme-mediated cytotoxicity in the control and eventual clearance of viral infections has been demonstrated in various perforin-deficient mouse models, in which animals failed to clear LCMV or Ebola virus.

While granule exocytosis is the dominant mechanism of cytotoxicity, it can also be mediated by the interaction of death ligands (Fas-ligand and TNF-related apoptosis-inducing ligand, TRAIL) on CD8 + and CD4 + T cell effectors with the death domain on receptor-bearing target cells, leading to caspase activation and apoptosis. This process is slower than granule exocytosis. Its role in the control of human viral infections is uncertain, however, *in vitro* studies have suggested that diverse viruses can trigger death receptor-mediated responses (examples being IAV, HPV, EBV, HSV, HCV, West Nile virus (WNV), and HIV-1).

Contraction of Cellular Immune Responses and the Formation of Immune Memory

After clearance or control of a viral infection the effector immune response must contract in order to avoid excessive inflammation and tissue damage. This self-limiting process is fundamental to the prevention immune-mediated disorders. It is achieved by the elimination of the majority (>90%) of effector CD4 + and CD8 + T cells via programmed cell death (or activation-induced cell death). In addition, up-regulation of co-inhibitory receptors (eg. programmed death-1, PD-1, and cytotoxic lymphocyte associated protein-4, CTLA-4) on effector cells leads to inhibition of activation when these proteins interact with their respective ligands on APCs, preventing further T cell proliferation and cytokine production. Following contraction, the surviving cell population assumes a memory phenotype and is maintained by homeostasis in the absence of re-infection.

Immunological memory, a hallmark of adaptive immunity that has evolved to provide a rapid and robust response to previously encountered pathogens, is achieved by maintenance of a small number of T cell clones. They are typically long-lasting and can persist throughout life. Memory T cells can be broadly categorized as either effector (T_{em}) and central memory (T_{cm}) T cells, according to the expression of the lymphoid homing and adhesion receptors, CD62 ligand (L-selectin) and CCR7. These are expressed on T_{cm} , enabling them to migrate to secondary lymphoid organs where they await recall stimuli, while T_{em} recirculate, acting as sentinels for previously encountered antigens. T_{em} retain some effector functions and are therefore poised to respond to invading pathogens. In contrast T_{cm} have superior proliferative capacity and can replenish the T_{em} population.

The Humoral Immune Response to Viral Infections

B Cells are the Drivers of Humoral Immunity

B lymphocytes develop in the bone marrow from hematopoietic stem cells via the common lymphoid progenitor that also gives rise to T cells. However, unlike T cells they continue their maturation in the bone marrow. Starting out as pro-B cells expressing the pro-BCR complex they quickly upregulate recombination-activating genes and undergo somatic rearrangement of gene segments in the variable region of the Ig locus, a process known as VDJ rearrangement. The resulting pre-B cells undergo further gene rearrangement leading to the expression of either kappa (κ) or lambda (λ) light chains, which are components of a functional B cell receptor (BCR). At this stage, the BCR is a membrane-bound IgM receptor. Immature B cells expressing IgM are tested for affinity to bone marrow-derived antigens in a similar manner to the T cells in the thymus, i.e., those that do not express a functional receptor die, while those responding with high affinity to self-derived antigens are either deleted or undergo receptor editing. Following this selection process, B cells leave the bone marrow as transitional immature B cell and enter the circulation. Through the process of alternative splicing, the IgM receptor is edited to produce IgD + naïve B cells. As for T cells, activation of naïve B cells occurs upon detection of specific antigen, either in a soluble form or presented by APCs, by the BCR. The B cell activation threshold is determined by the affinity of the BCR and dose of antigen as well as innate signals present at the time of activation. The activated B cell then mounts a T cell-dependent (TD) or T cell-independent (TI) immune response depending on the molecular composition of the activating antigen. Polysaccharides and lipid-based antigens typically induce a TI B cell response, with the production of rapid but short-lived antibodies. Structurally, they are composed of repeating antigens, which enables cross-linking of BCRs. Marginal zone B cells and B-1 cells, which are a subset of B lymphocyte expressing a more limited BCR

repertoire, all participate in TI responses. While more typically associated with antibody responses to bacteria, they are also elicited by highly glycosylated glycoproteins, such as the viral envelope of HIV-1. Protein antigens, by contrast, activate B cells to mount a TD antibody response, which leads to the production of long-lived class switched antibodies that arise much later than TI antibodies.

A TD B cell response is elicited by the BCR-mediated capture of antigen by follicular B cells or B-2 cells from follicular dendritic cells in the germinal centers of lymphoid tissue. Follicular B cells function as professional APCs by processing and presenting the antigen in the context of MHC class II to Tfh or Th2 cells. Activated follicular B cells upregulate the T cell zone homing receptor, CCR7, while downregulating CXCR5 to enable migration to the T cell: B cell border, where they interact with pre-Tfh cells. The cognate engagement between the TCR on Tfh cells and peptide-MHC II on follicular B cells, together with CD40 with CD40L and inducible T cell co-stimulator (ICOS) with ICOS ligand (ICOSL), induces signals that promote their survival and further differentiation to Tfh and GC B cells respectively. Activated B and Tfh cells are then able to migrate to follicles in a CXCL-13 dependent gradient where they form GCs to induce GC reactions. Here, B cells clonally expand and undergo affinity maturation of immunoglobulin receptors through the process of somatic hypermutation (SHM). SHM involves editing of the Ig V domain by AID and generates Igs with a higher affinity for their cognate antigen. Secreted Igs, or antibodies, consist of the two heavy chains and two light chains of the BCR, with the V domains (also known as the variable fragment, Fv) forming the antigen-binding region, and constant domains (Fc), that determine the antibody effector function through interaction with innate immune cells bearing Fc receptors. The Fv domains contain hypervariable regions, or CDRs, that contact the antigen surface. As the two Fv domains are identical, this increases antibody avidity to its target antigen. SHM is followed by class switch recombination (CSR) to generate other classes of antibodies (IgG, IgA, and IgE) with a wider range of effector function and tissue localization. The factors critical for initiating CSR include BCR signaling, AID expression, antigenic dose as well as cytokines like IL-4, TGF- β and in mouse models, IFN- γ . Protein antigens, including those expressed by viruses, typically generate IgG (specifically IgG1, 2a and 3 sub-classes) and IgA and can also elicit IgM. The terminal stage of the GC reaction involves the differentiation of GC B cells into long-lived plasma cells that mediate antigen-specific effector responses via the secretion of antibodies, and memory B cells which differentiate rapidly into plasmablasts upon re-exposure to antigen (Fig. 2).

Extrafollicular B cells have also been described that are activated in either a TD or TI manner. These cells migrate to an extrafollicular location where they form a focus of cells secreting robust but short-lived antibodies. They have been described in a number of viral infections including SIV and HIV-1.

Antibodies Play an Essential Role in Antiviral Humoral Immunity

There are three main effector functions of antibodies that play an important role in curtailing viral infections.

Neutralization

Antibodies that block viral entry or reduce viral replication are described as having neutralizing activity. This effector function is mediated by the binding of the Fv region of antibodies to viral antigens. Neutralizing activity is considered to be a crucial component of adaptive immunity as it is strongly correlated with protection against re-infection and with vaccine-induced immune protection. While it typically involves inhibition of viral attachment or fusion with the host cell receptor, it is not defined by a particular mechanism but is an *in vitro* measure of the interaction between a virus and its host cell. The discovery of post-fusion neutralization in the context of influenza virus infection illustrates that the underlying mechanisms may be more diverse than had been appreciated. The targets of neutralizing antibodies are typically exterior proteins that make up the viral envelope or capsid. Neutralizing activity can be demonstrated in sera from individuals who have successfully controlled viral infections. However, they are also found in chronic infections such as HIV-1 and HCV. In this context, the failure of neutralizing antibodies to contain the infection is a consequence of multiple immune evasion mechanisms, including the slow development of antibodies that recognize diverse antigenic determinants in the viral envelope (broadly neutralizing antibodies or bNAbs) in the face of rapid viral evolution.

Opsonization

Secreted antibodies can bind to viral targets either on infected cells or free virus particles, coating these targets in a process known as opsonization, which mediates antibody-dependent cellular phagocytosis (ADCP) by macrophages and neutrophils, or activation of the classical complement pathway. Binding of the first component of the complement system triggers a cascade of protease activity, resulting in the formation and deposition of a membrane attack complex on the virus or viral protein, causing its destruction. Complement-mediated neutralization has been described in a wide range of viral infections. A notable example is Ebola virus disease (EVD), in which antibodies from survivors exhibited IgG and IgA-mediated innate immune effector functions *in vitro*, including ADCP. Opsonization may also play a role in pathogenesis, for example by enhancing viral infection of DCs via complement receptors, as has been described in HSV-2.

Fig. 2 The germinal center reaction. Antigen-primed CD4 T cells destined to become Tfh cells migrate to the T:B cell border where they interact with primed cognate B cells. Tfh and B cells then migrate to form the GC composed of two distinct microanatomical sites – LZ and DZ. Within the DZ, B cells proliferate and undergo SHM before cycling into the LZ, where high affinity B cell clones get survival signals from Tfh cells and FDCs, and undergo CSR. Cycling between the DZ and LZ continues, leading to the eventual selection of high affinity centrocytes that exit the GC as antibody-secreting plasma cells or memory B cells. GC, germinal center; DZ, Dark zone; LZ, Light zone; FDC, Follicular dendritic cells; CSR, Class switch recombination; SHM, Somatic hypermutation.

Antibody-Dependent Cellular Cytotoxicity (ADCC)

Following binding of the antibody Fab region to viral antigens, binding of the exposed Fc region by Fc receptor (FcR)-expressing cells can initiate direct cell lysis in a process known as ADCC. FcR are found on all innate immune cells and are defined according to their specificity for different antibody subclasses (FcγR – IgA, FcεR – IgE, and FcγR – IgG). On NK cells, the crosslinking of FcγRIIIA (CD16) mediates ADCC. This effector function was shown to be important in the immune response to influenza over 40 years ago. Recently, it has emerged that HIV-1-specific bNAbs may be capable of inducing ADCC, suggesting a greater breadth of effector function for these antibodies, that develop in a minority of individuals during chronic infection. Furthermore, vaccine-induced ADCC has been associated with the modest protection found in the sole HIV-1 vaccine trial that has shown any protective efficacy to date (the Rv144 trial).

Induction of Immunity to Viruses by Vaccination

Vaccination has been used for over 200 years to protect from infectious diseases. The introduction of vaccination against common childhood viral and bacterial infections during the course of the 20th century led to dramatic declines in mortality in children under 5 years of age. The eradication of smallpox (caused by Variola virus) using the live VACV vaccine (from which the intervention takes its name) is one of the most significant achievements in the history of medicine. For decades, many successful vaccines were developed empirically, using whole organisms that were attenuated in cell culture or inactivated by heat or chemical treatment to render them safe for human use (Table 2). The mechanisms of immune protection, and the pathogen components necessary to achieve this, were incompletely elucidated in many cases. However, protection could be demonstrated in animal models by passive transfer of blood components containing antibodies or cells to naïve animals, which were then subjected to pathogenic challenge. The advent of recombinant DNA technology led to the production of the first subunit vaccine against a

virus: recombinant HBV surface antigen, a component of the viral envelope, is one of the most successful vaccines to date. In parallel, advances in molecular and cellular technologies have enormously enhanced our understanding of the mechanisms involved in vaccine-induced and natural immunity. The insights gained have been translated into new and improved vaccines.

Over the past decade, high-throughput ‘omics’ approaches have been applied to the study of the human immune response to viruses, using vaccinated individuals as a model of effective immunity. These ‘systems biology’-based studies of the response to vaccines against yellow fever virus (YF-17D) and seasonal influenza highlighted the importance of engaging the innate immune system, via PAMP-PRR interactions, in order to achieve an effective adaptive immune response. Furthermore, induction of potent CD8 + T cell responses appears to be dependent on an acute viral infection, which is achieved with live attenuated viral vaccines such as YF-17D and measles/mumps/rubella. Strong CD8 + T cell responses are also induced with vaccine candidates based on replicating or replication-deficient viral vectors that have limited host range or have undergone targeted gene deletion. This strategy mimics an acute viral infection, with activation of PRRs by PAMPs in the vector following a single round of infection in target cells, and the desired antigen-specific response is induced by expression of the transgene in these cells. The factors that contribute to the induction of strong and durable antibody responses are less clear. Smallpox vaccinees have stable antibody levels for up to 75 years after vaccination, together with long-lived VACV-specific memory B cells. YF-17D also induces virus-specific neutralizing antibodies that can last for several decades. These observations suggest that the ‘acute viral infection’ engendered by live attenuated vaccines is important for induction of durable antibodies. However, human papillomavirus (HPV) virus-like particle (VLP) vaccines, which have proven highly effective against infection with oncogenic and non-oncogenic HPV types, comprise multimerized capsid proteins only, yet they induce neutralizing antibody titers that are several orders of magnitude higher than naturally-induced antibodies and persist for at least 10 years. This is achieved in part by administration with potent adjuvants, such as the TLR4 agonist monophosphoryl lipid A, and also by the structure of the VLPs, which contain epitopic repeats that are a typical feature of PAMPs.

There are still significant challenges in the development of vaccines for many viruses (Table 3). These relate to immune evasion properties such as antigenic variation, the capacity to establish latency or to co-opt host tolerance mechanisms, and the lack of a defined correlate of protection against natural infection. In addition, some vaccine strategies have unexpectedly increased the risk of disease through mechanisms such as antibody-dependent enhancement of infection. In the case of emerging pandemic viruses such as the novel coronavirus, SARS CoV-2, the protective effect of natural immune responses is not yet known, and it is currently

Table 3 Challenges in vaccine development and possible solutions under investigation

<i>Challenges in vaccine development</i>	<i>Possible solutions under investigation</i>
Antigenic diversity ● Rapid mutation as a result of error-prone reverse transcriptase of viruses, leading to within-population and intra-subject antigenic diversity. Mutations also enable escape from host cytotoxic T cell and antibody-mediated responses	● Use of consensus or mosaic immunogen sequences to improve breadth of viral strain coverage and immunogenicity of vaccines ● Modified vaccination strategies including sequential vaccination to mimic virus/antibody co-evolution leading to induction of bNAb development by vaccination and/or the design of immunogens that activate germline precursors of bNAbs to initiate antibody affinity maturation ● Improved mapping of bNAb epitopes on conserved regions of envelope protein for vaccine development to induce bNAb by vaccination ● Development of a universal vaccine capable of broad cross reactivity by increasing breadth of neutralizing antibodies by targeting HA stalk and conserved regions in HA head domain for Influenza vaccines ● Optimized vaccination strategies that induce and maintain CTLs at portal of viral entry prior to virus dissemination
Structural complexity of envelope protein, limiting epitope availability and antibody recognition ● Some viruses like HIV show extensive glycosylation on Env protein. This masks conserved epitopes shielding them from antibody binding ● Conformational changes in envelope protein leading to transiently exposed epitopes or complex conformation ● Structural flexibility of envelope proteins also hampers the mapping of these epitopes	● Use of stabilised Env trimers for vaccination to mimic antigenic surfaces of native trimer ● Focus vaccine development efforts to target conserved non-structural (NS) proteins which induce greater breadth in T cell responses
Poor immunogenicity of certain proteins and vaccination platforms ● Hypervariable regions of envelope protein of viruses like HIV are highly immunogenic while conserved regions are poorly immunogenic. Highly immunogenic regions create a diversionary effect (decoy) from immune response against conserved regions. ● Safety issues associated with live-attenuated vaccination platform ● Whole killed viruses and subunit vaccines not immunogenic	● Use of viral vector vaccination platforms to improve induction of CTLs ● Optimized vaccination strategy to improve immunogenicity and efficacy of various vaccination platforms and regimen inducing broad and potent T cell responses and/or antibody mediated protection e.g. targeting NP and M1 in influenza virus
Lack of appropriate models for vaccine development and testing ● Existing in vitro culture models and/or small animal models do not recapitulate human infection by HIV, HCV and ZIKV ● Absence or poorly defined correlates of protection in natural infection, vaccine trials and virulence factors ● Sporadic and unpredictable epidemics and declining incidence rate causing significant impact on evaluation of vaccine efficacy in clinical trials	● Establishment of human challenge infection models (CHIM) to test efficacy of developed vaccines although this poses ethical issues including the possible development of complications like Guillain-Barre syndrome in ZIKV infection ● Use of humanized small animal models, where possible
Host immunoregulation of bNAb development ● HIV bNAbs are elicited rarely and only in chronic infection, due to requirement for high degree of somatic hypermutation and long HCDR3 regions; these are normally constrained by host tolerance mechanisms	● Transient modulation of immune checkpoint receptors during vaccination to enable bNAb generation
Integration into cellular DNA during primary infection and persistence in latent state in long-lived CD4⁺ T cells	● Therapeutic vaccination strategies involving a 'kick' to reactivate latent HIV virus reservoir followed by a kill of virus infected cells
Antibody-dependent enhancement of infection or disease (ADE) ● Antibodies show cross-reactivity with other flaviviruses facilitating infection (also poses diagnostic challenges) in locations where several other flaviviruses are endemic	● Optimization of the design of vaccine platforms that abrogate ADE e.g. unrelated viral vector (ChAdOx1) for delivery of ZIKV antigens used in mouse studies of ZIKV vaccination

Abbreviations: HA, Haemagglutinin, NHP, Non-human primates.

unclear whether prior infection with related coronaviruses induces cross-protection. Addressing these questions may be crucial to developing an effective vaccine.

Dysregulation of Immune Response to Viruses

Immune dysregulation can manifest as loss of immune effector function, which leads to disease resulting from loss of control of viral replication, or over-activity resulting in damage to healthy tissues.

The importance of type 1 IFN (IFN-I) in orchestrating innate and adaptive immune responses to virus was discussed earlier. However, in chronic infections persistent expression of IFN-I and ISGs may be a double-edged sword: observational studies showed an association between upregulation of ISGs and faster progression of HIV-1 disease or poor control of viral replication. Consistent with this, comparative studies of SIV infection in sooty mangabeys, which do not develop sustained CD4⁺ cell loss despite acute viremia, and Rhesus macaques, which develop acquired immunodeficiency syndrome, showed that the former rapidly attenuate IFN-I expression after acute infection.

Viruses that are able to persist by establishing latency, with periodic gene expression and virion production, can cause chronic immune activation through persistent antigenic stimulation. This is accompanied by progressive loss of functional capabilities of virus-specific CD4⁺ and CD8⁺ effector T cells, including reduction in cytokine secretion and cytotoxic capability, the upregulation of immune co-inhibitory (checkpoint) receptor expression such as PD-1, CTLA-4, T cell immunoglobulin mucin-3 (TIM-3), lymphocyte-activation gene 3 (LAG-3), on the surface of cells, a dysregulated response to homeostatic cytokines IL-7 and IL-15, metabolic dysregulation and epigenetic changes resulting in the expression of transcription factors associated with dysfunction such as eomesodermin, basic leucine zipper transcription factor, ATF-like (BATF), T-bet and nuclear factor of activated T cells (NFAT). This phenomenon is well described in chronic HBV, HCV, and HIV-1 infections. It can be reversed to some degree by treatment with specific immune checkpoint receptor antagonists and/or with antiviral agents that block viral replication, thereby removing the antigenic stimulus.

Given the importance of CD4⁺ T cell help in coordinating and optimizing CD8⁺ T cell and B cell responses to viruses, infections that directly compromise CD4⁺ T cell function lead to profound dysregulation of immune responses, HIV-1 being a

Fig. 3 Immune response to a virus. Invading viruses first encounter phagocytic cells (neutrophils and macrophages) and dendritic cells, triggering non-specific innate immune responses that aim to contain the infection. Dendritic cells capture viruses or virally infected cells and process antigens for presentation to CD4⁺ T cells, CD8⁺ T cells and B cells, priming adaptive immune responses. CD4⁺ T cells provide help to B cells to make antibodies and to CD8⁺ T cells to mature into fully functional effectors. A successful immune response ends with the clearance or control of the viral infection, contraction of the T and B cell responses and development of immunological memory. Failure to contain the infection may result in persistent viral antigen production, leading to immune exhaustion whereby T cells lose their ability to respond effectively to viruses. IFN γ , Interferon- γ ; TNF- α , Tumor necrosis factor- α ; CD, Cluster of differentiation; MHC, Major histocompatibility complex.

prime example. In chronic HIV-1 infection, loss of T_{fh} help severely impairs GC responses, resulting in reduced plasma cell numbers, a failure to class switch antibodies and slow development of bNAbs. In addition, cytotoxic CD4 + T cells can impair antibody responses by deleting marginal zone B cells and macrophages. Conversely, a reduction in Treg frequencies in chronic infection was associated with the emergence of bNAbs, which are normally under host tolerance constraints regulated by Tregs due to their resemblance to self-antibodies. Increased numbers and functional activity of Tregs have also been reported to play a role in the impairment of virus-specific CD4 + and CD8 + T effector responses in chronic HCV infection.

Conclusions

Here, we have discussed the multi-layered nature of the immune response to viruses primarily from a human perspective. However, the immune system has evolved over hundreds of millions of years, from primitive phagocytic cells that are found in invertebrates to the emergence of antigen-specific lymphocyte receptors in vertebrates to the complex cellular and molecular networks described in this article.

The key components of antiviral immunity are: (1) a physical, chemical and microbial barrier that limits viral entry; (2) innate sensing of viruses that breach this barrier by phagocytic cells possessing an array of polyspecific receptors, which initiates an immediate signaling cascade that serves to restrict viral replication and to recruit and activate NK cells; (3) priming of adaptive immune responses through the interactions of professional APCs with CD4 + T cells, CD8 + T cells and B cells; (4) maturation of antigen-specific responses by these effector population; (5) survival of a subset of antigen-specific T cells and B cells to provide immunological memory and thus protect against re-infection (Fig. 3).

Since many viruses have co-evolved with their hosts, elucidation of the mechanisms they use to overcome each layer of immune defense has led to deeper insight into the complexity of the innate and adaptive immune systems. These discoveries continue to provide opportunities to develop new and better therapeutics and vaccines, while also revealing the significant challenges that have yet to be overcome. At the time of writing, a pandemic caused by the novel coronavirus, SARS-CoV-2 has affected nearly 3 million people, with over two hundred thousand losing their lives. While its close genetic relationship to an earlier outbreak pathogen, SARS-CoV, enabled rapid determination of the basic aspects of its biology and life cycle, the exponential spread of SARS-CoV-2 demands that the mechanisms underlying both the pathogenesis and the development of natural immunity be deciphered in real time. Critical questions will be to determine how long any immune response may last, whether it is sufficient to prevent re-infection and whether a vaccine can be developed to provide durable protection.

Introduction

Antigenicity reflects the pattern of antibody responses which the host develops against a virus. For each virus, the host develops an array of distinct antibodies derived from an array of germline segments and usually refined by somatic mutation to include some with high affinity for the antigen. The particular structural regions of proteins recognized by these antibodies are designated as antigenic sites. Upon re-exposure to the viral antigen, the host immune memory reacts promptly and efficiently to produce high-affinity antibodies, which contributes to antibody-mediated immunity and a reduced risk of severe infections in the host. Under the principle of natural evolution, the virus evolves to adapt to survive pressure from the environment and host through the generation of genetic diversity. Since many viruses have a very high mutation rate this generally occurs quickly and the accumulation of genetic mutations potentially results in the modification of viral structural proteins. Antibody recognition occurs over a reasonably extensive area of the protein surface (the antibody footprint) but within this region changes in individual key residues might completely prevent recognition, for instance a larger side chain may sterically block antibody engagement, this would be an escape mutation. By improving the survival fitness of the virus, such structural changes located at or near the antigenic site will lead to the emergence of these antigenic variants in the host and environment.

The outer structural proteins often play a key role in the engagement with cellular receptors and the initiation of the entry into the host cell. Based on their outer structure, viruses can be classified into enveloped and non-enveloped viruses. An enveloped virus is constructed with a lipid bilayer membrane and the presence of surface-exposed glycoproteins. Non-enveloped viruses comprise a capsid built of assembled protein subunits. The exposed glycoprotein of enveloped viruses and the capsid of non-enveloped viruses are the principal targets of host antibodies and thus comprise the primary antigenic sites of viruses.

In most cases, viral antigenicity is analyzed based on post-infection animal sera and monoclonal antibodies. The analysis of escape variants with polyclonal antisera and monoclonal antibodies helps to define neutralizing antigenic sites and trace antigenic variation in the circulating strains. Recent advances in identifying and producing human monoclonal antibodies greatly facilitate the identification of antigenic sites and antigenic variants of human pathogenic viruses, which is of great value in virological surveillance and vaccine development.

The following sections will further explain and exemplify viral antigenicity and antigenic variation in several enveloped and non-enveloped human pathogenic viruses.

Influenza A Virus Hemagglutinin

Influenza A virus is an enveloped RNA virus that infects 5%–10% of the world population each year and kills about half a million people. Antigenicity of the influenza A virus resides in its surface membrane-embedded glycoproteins, mostly hemagglutinin (HA) and, to a lesser extent, neuraminidase (NA). At the moment two major antigenic types of influenza A virus, H1N1 and H3N2 (named after the type of HA and NA they use), are circulating that are clinically relevant to humans. Other antigenic types and their combinations are mainly found in the natural viral reservoir in animals and can occasionally undergo reassortment during a co-infection, which is facilitated by the segmented nature of the viral genome. Such genetic reassortment can potentially lead to the emergence of a radically different and novel antigenic variant, this is called antigenic shift, and it can lead to a severe pandemic, as was caused in 2009 by swine influenza H1N1.

A less dramatic but profoundly important phenomenon observed with influenza A virus is its progressive, unidirectional evolution in which gradual genetic changes accumulate in the HA antigen, a process called antigenic drift. Once mutated, the new antigenic protein is incorporated into new virus particles to be selected for their fitness in terms of survival, infectivity and the capacity to escape antibody recognition. While virus-specific antibodies produced by the immune system can prevent re-infection by a particular virus strain, these antibodies also generate an additional selection pressure to favor escape mutations in the antigen proteins for the virus to survive. Surviving viruses then become a new strain, circulate back in the population and infect individuals without adequate protection. This cycle iterates year after year, driving the direction of antigenic drift and resulting in an influenza-unique evolutionary pattern, in which new antigenic variants are constantly evolving and the old ones never seem to return.

On influenza A viruses, major antigenic sites are found on the surface HA which is a homotrimer with a moderate-to-heavy N-glycosylation profile. Each of its monomers consist of two chains, HA1 and HA2, which are linked by two disulfide bridges (**Fig. 1(a)**). Structurally, the membrane-distal globular head of HA1 binds to cellular surface sialic acid glycans for viral attachment and entry, and a cylinder-like HA2 stem near the membrane refolds into an extended helical bundle to mediate the fusion between

Fig. 1 Antigenic variation of influenza A H1N1 hemagglutinin. (a) Protein structure of influenza A H1 HA (PDB code 3UBJ) is shown as a homotrimer, with each monomer colored differently. Each monomer consists of two chains, HA1 and HA2, the latter in darker colors. Its glycan-binding site is near the top of the head region, and the ligand (LSTa) is shown as spheres colored by atom (gray for carbon and red for oxygen). (b) Classical antigenic sites of HA in the head region are shown in pink (Sa), yellow (Sb), green (Ca) and teal (Cb). Sites in the stem region are also recognized by recently developed neutralizing antibodies, CR6261 (light blue) and CR8020 (dark blue) as examples. (c) A phylogenetic tree of A/H1N1 HA evolution provided by nextstrain.org using data from GISAID shows a progressive pattern from 2009 to now, colored by dates, with each dot denoting a specific strain. (d) Mapping amino acid diversity on influenza A H1 HA structure using entropy data from GISAID, with darker red showing highly variable amino acids and white highly conserved amino acids. Comparison between different time courses reveals an overall consistent pattern of amino acid diversity over different lengths of time, with a few hotspot sites appearing at some time and remaining diversified. All HA structures were drawn using surface representation using ChimeraX, with identical viewing angles.

viral and endosomal membranes for the release of virus genome into the cytoplasm. There are four classical antigenic sites in the HA1 head domain, defined as Sa, Sb, Ca1/Ca2, and Cb (Fig. 1(b)), which have been characterized using escape mutants and monoclonal antibodies. Antibody-binding sites are also found in the HA2 stem region, spanning both N-terminal regions of HA1 and HA2 (Fig. 1(b)), and antibodies binding to these sites inhibit viral fusion resulting in nonreproductive viruses which are eventually cleared by host cells. In the case of influenza A H1N1 virus, progressive accumulations of mutations have occurred in the HA protein throughout the years, generating numerous new strains from the 2009 pandemic to now (Fig. 1(c)). It is noted that some mutation hotspots on HA overlap with or locate close by known antigenic sites (Fig. 1(d)), suggesting an escape mechanism whereby pre-existing antibodies will no longer bind as strongly to the new antigenic variants. At the same time, mutations are also observed in the stem region which was originally thought as highly conserved, and although less-likely it is possible that the efficacy of stem-binding neutralizing antibodies may be reduced as the protein continues evolving in the future.

Dengue Virus Envelope

Dengue virus (DENV) an enveloped RNA virus, is an arthropod-borne human viral pathogen that causes dengue fever epidemics in tropical and subtropical areas every year. DENV is categorized into four distinct antigenic serotypes (DENV1–4), which are further divided into different genotypes. Within each DENV antigenic type, genetic and antigenic diversity exists which results in multiple distinct genotypes.

Primary infection with one DENV serotype has been shown to provide life-long immunity against a similar serotype and short-term immunity against other serotypes. A longitudinal survey of DENV clinical strains over a 20-year time span from Bangkok, where all four DENV serotypes have co-circulated suggests the extinction of one clade and the replacement with another. These shifts have been shown to be linked to the epidemic cycle in the region.

Anti-envelope human antibodies are primarily directed against two glycoproteins on the surface of the viral envelope, the precursor membrane (pre-M) and envelope (E) proteins. Genetic diversity of pre-M and E proteins can significantly modulate antibody neutralization activity against DENV2 strains. Antigenic variation in the E protein has also been shown to impact the neutralization efficiency of monoclonal antibodies, antisera from DENV-infected patients, and immune sera from DENV-vaccinated individuals. Additionally, DENV serotypes contain antigenic heterogeneity. Mapping of E protein amino acid differences from different DENV antigenic serotypes revealed four distinct clusters whereby each serotype was clustered closely together on the antigenic map. However,

Fig. 2 Antigenicity of HIV-1 envelope glycoprotein gp160. (a) The HIV-1 envelope glycoprotein trimer, composed of gp120 and gp41 proteins. The figure demonstrates the closed conformation of the envelope protein. (b) Conserved neutralizing antigenic sites, including the first and second variable loop (V1/V2) of gp120, the third variable loop (V3), the CD4 binding site (CD4bs), the gp120-gp41 interface and the membrane proximal external region (MPER) of gp41, on the envelope glycoprotein. Examples of broadly neutralizing antibodies are presented in parentheses.

cross-reactivity of antisera with different serotypes can lead to discrepancies in the DENV antigenic cluster and certain DENV strains have shown more antigenic variance to inter-typic viruses than intra-typic viruses.

Antigenic characterization of DENV would greatly aid in DENV vaccine development. In order to promptly identify DENV antigenic variants, an in-silico model for DENV has been devised based on possible antigenicity-dominant positions of the E protein providing a convenient way to calculate the difference in viral antigenicity.

Human Immunodeficiency Virus Type 1 Envelope Glycoprotein

Human immunodeficiency virus type 1 (HIV-1) is an enveloped RNA virus and causes millions of infections around the world. HIV-1 binds and infects the host cell via the envelope glycoprotein gp160 anchored at the viral surface. The gp160 protein is a trimer of heterodimers containing glycoprotein 120 (gp120) and transmembrane glycoprotein 41 (gp41) (Fig. 2(a)). The gp120 protein is responsible for binding to CD4 cellular receptor and another co-receptor (CCR5 on macrophages and CXCR4 on T cells) and conformational changes in the gp41 protein are critical for membrane fusion and cell entry. The gp160 protein is the primary target of human neutralizing antibodies.

After infection with HIV-1, an autologous neutralizing antibody response is directed towards the envelope glycoprotein of the transmitted/founder virus. Antibodies to the envelope commonly recognize the exposed loops of gp120 and this drives the high evolutionary rate of the envelope protein. The rapid development of escape variants allows the virus to evade autologous neutralizing antibodies and the virus ends up developing into a variety of strains, also known as the “quasispecies”. Therefore, an HIV-1-infected person usually fails to establish sterile immunity and finally develops a chronic infection.

There are several mechanisms that allow antigenic variation to occur with high frequency within the HIV-1 virus. It has been noted that a single amino acid substitution, or sequence insertion or deletion, at the antigenic site of envelope glycoprotein can result in neutralization escape. Additionally, the abundance of glycans (N-linked glycosylation) on the outer surface of the gp120 protein can also shield the antigenic sites from antibody.

While autologous strain-specific neutralizing antibody response to viral envelope glycoprotein is generally described and the escape of HIV-1 is characterized by a marked genetic and antigenic divergence within strains, broadly reactive neutralizing antibody can be occasionally detected in a subset of infected persons. Many efforts have been made to delineate antigenic sites recognized by broadly neutralizing human antibodies and several conserved antigenic sites, including the first and second variable loop (V1/V2) of gp120, the third variable loop (V3), the CD4 binding site (CD4bs), the gp120-gp41 interface and the partially lipid membrane embedded membrane proximal external region (MPER) of gp41 have been reported (Fig. 2(b)).

Vaccine design has focused on eliciting neutralizing antibodies to the monomeric gp120, but this vaccine fails to demonstrate efficacy in clinical trials. Recently, the identification of conserved antigenic sites had led to the development of novel vaccine antigen for inducing broadly neutralizing antibodies. For example, a new candidate vaccine containing the soluble stabilized SOSIP trimer that mimics the native envelope has been developed and broadly neutralizing antibodies can be successfully induced in immunized animals. This epitope-focused vaccine design provides a new prospect for a preventive HIV-1 vaccine.

Enterovirus A71 Capsid

Enterovirus A71 (EV-A71) is a non-enveloped RNA virus and one major cause of outbreaks of hand-foot-mouth disease in children. The viral capsid of EV-A71 is composed of VP1, VP2, VP3 and VP4 proteins. VP4 is buried inside the capsid. Antigenic sites have been identified on the VP1, VP2 and VP3 proteins based on murine and human antibodies.

EV-A71 is classified into three genogroups (A-C), which can be further divided into 11 genotypes (A, B1-B5, C1-C5) based on the sequence variations of the VP1 gene. Human antisera show varied neutralization titers against different genotypes of viruses. Antigenic cartography showed antigenic diversity and distinct clustering among the genotypes. Genotypes B1 and B4 are clustered closely together, genotypes C2 and C4 form another cluster, while genotype B5 has been shown to form a distinct cluster of its own. This suggests a difference in EV-A71 antigenic properties and antigenic diversity within strains. Antisera from EV-A71-infected rabbits, mice, guinea pigs, and patients also demonstrate various neutralization titers against different EV-A71 genotypes, supporting the finding of antigenic variation among these viruses. The change in viral antigenicity has been linked to antigenic sites within the VP1 region. Amino acid residues VP1-98, -145, and -164 have been reported as antigenic sites for genotypes B4 and B5 EV-A71. Antigenic changes did not result from single amino acid mutations alone but instead were the result of all three mutations working in a cooperative manner.

Human antisera have varied neutralization titers against reassortant viruses containing different combinations of mutations at VP1-98K, -145Q and -164E, respectively.

Although human antisera may exhibit varied neutralizing activities with different genotypes of viruses, in most cases, cross-neutralization is detected in human sera.

Several antigenic sites on the EV-A71 capsid recognized by a panel of neutralizing human monoclonal antibodies have been identified and characterized in detail. These antigenic sites are found to be conserved among genotypes B and C EV-A71 viruses isolated in the recent decade.

Conclusion

Antigenic variation is a common strategy used by a broad range of viral pathogens to avoid host immune responses. Nevertheless, the rate of genomic mutation and the diversity of antigenic variants vary markedly among different viral species. Viral antigenicity is tightly linked with the capacity of a virus to be bound by specific antibodies, especially neutralizing antibodies. The understanding of antigenicity and associated antigenic change in the virus aids the design of protective vaccines. However, vaccines may have varying efficacy largely resulting from hard-to-predict antigenic variation, as seen for example in influenza A virus and human immunodeficiency virus type 1.

Introduction

The immune system is responsible for the tremendous task of fighting a wide range of pathogens to which we are constantly exposed. This system can be broadly subdivided into innate and adaptive components. The innate immune system exists in both vertebrate and invertebrate organisms and represents the first barrier against microbial invasion. This arm of the immune system rapidly eliminates the vast majority of microorganisms that we daily encounter and is responsible for limiting early pathogen replication. The adaptive response is a more sophisticated feature of vertebrate animals involving a broad repertoire of genetically rearranged receptors that specifically recognize microbial antigens (antigen is a generic term for any substance that can be recognized by the adaptive immune system). The hallmark of the adaptive response is the generation of a potent and long-lasting defense specifically directed against the invading pathogen.

B and T lymphocytes represent the effector players of adaptive immunity and carry on their surface antigen-specific receptors, B-cell receptors (BCRs) and T-cell receptors (TCRs), respectively. There are two major classes of T lymphocytes: CD8 cytotoxic and CD4 helper T cells. Upon antigen encounter, lymphocytes undergo clonal expansion and differentiation of their unique functional features. B cells differentiate into plasma cells and secrete antibodies that specifically bind the corresponding antigen. CD8 T cells directly kill infected cells or release cytokines that interfere with viral replication, while CD4 T cells activate other cells such as B cells and macrophages. Unlike B cells, which can directly bind native free antigen, T cells only recognize antigen-derived peptides displayed on cell surfaces in the context of major histocompatibility complex (MHC) class I (MHC-I, CD8 T cells) or class II (MHC-II, CD4 T cells) molecules.

Different pathogens preferentially replicate in distinct cellular compartments. While viruses and intracellular bacteria replicate in the cytosol, microbes such as mycobacterium and protozoan parasites are intravesicular and colonize the endosomal and/or lysosomal compartments. In addition, extracellular bacteria release antigens, such as toxins, that are engulfed by antigen-presenting cells (APCs) to also reach the endosomal pathway. Antigenic peptides derived from these sources are exhibited on cell surfaces by MHC molecules. This process, which represents the major focus of this article, is named 'antigen presentation' and is a fundamental pillar of antimicrobial host defense.

Antigen-Presenting Cells

For initiation of an immune response, naive T cells need to be activated or 'primed'. For that, they require both the recognition of the specific MHC-peptide complex (signal 1) and simultaneous costimulation (signal 2). Although all nucleated cells express MHC-I and can potentially display MHC-I-microbial peptide complexes after infection, only a specialized group of leukocytes, named APCs, express both MHC-I and MHC-II as well as costimulatory molecules. The best-characterized costimulatory molecules are CD80 and CD86, which bind to the CD28 molecule on the T-cell surface. In addition, T cells express CD40 ligand, which interacts with CD40 on APCs further enhancing costimulation and enabling T-cell response. Finally, there is another group of adhesion molecules, such as lymphocyte function-associated antigen-1 (LFA-1) on APCs which binds to ICAM-1 on T cells that seal the APC-T-cell interface. During APC-T-cell interactions, all these molecules cluster together forming a highly organized supramolecular adhesion complex (SMAC), enabling the intimate contact between the two cells that is referred to as the immunological synapse (Fig. 1).

APCs are composed of macrophages, B cells, and dendritic cells (DCs). They differ in location, antigen uptake, and expression of antigen-presenting and costimulatory molecules. Macrophages are localized in connective tissues, body cavities, and lymphoid tissues. Within the secondary lymphoid tissues, macrophages are mainly distributed in the marginal sinus and medullary cords. They specialize in phagocytosis and engulf particulate antigens through scavenger germline receptors such as the mannose receptor. On the other hand, B cells form follicular structures within secondary lymphoid organs and recirculate through the blood stream and lymph seeking their specific antigen. B cells recognize antigens specifically through a rearranged BCR. DCs are the most professional and robust of the APCs. They are widely distributed through the body at an 'immature' stage of development, acting as sentinels in peripheral tissues. They continuously sample the antigenic environment by both phagocytosis and macropinocytosis, which is the engulfment of large volume of surrounding liquid. Within the secondary lymphoid organs, some DCs strategically localize within T-cell areas where they can optimally encounter circulating naive T lymphocytes that actively scan the DC network.

APCs are able to detect components of invading pathogens which trigger their activation/maturation. Specifically, pathogen-associated molecular patterns (PAMPs), as these components are termed, range from lipoproteins to proteins to nucleic acids

Fig. 1 Interactions between virus-specific T cells and APCs. Three-color confocal microscopy was used to demonstrate immunological synapse formation between lymphocytic choriomeningitis virus-specific T cells (blue) and MHC-II^b APCs (red) in the central nervous system. Immunological synapses were indicated by the polarization of the adhesion molecule LFA-1 (green) between the CTL and APC. Asterisks denote the engaged APC, and arrows denote the contact point between the two cells. LFA-1 is expressed on both CTLs and APCs, but note that all of the CTL-associated LFA-1 is focused toward a contact point at the CTL-APC interface. Reproduced from Lauterbach, H., Zuniga, E.I., Truong, P., Oldstone, M.B.A., McGavern, D.B., 2006. Adoptive immunotherapy induces CNS dendritic cell recruitment and antigen presentation during clearance of a persistent viral infection. *Journal of Experimental Medicine* 203 (8), 1963–1975, with permission from Rockefeller University Press.

carried by potential invaders. These PAMPs are recognized by evolutionarily conserved ‘pattern recognition receptors’ (PRRs) on APCs. Among PRRs, the Toll-like receptors (TLRs) have emerged as critical players in determining APC imprinting on the ensuing immune response. TLR triggering has pleiotropic effects on APCs, promoting survival, chemokine secretion, expression of chemokine receptors, migration, cytoskeletal and shape changes, and/or endocytic remodeling. After interacting with these pathogen signatures, the microbial antigens are processed and presented as peptides associated with MHC molecules and activated APCs upregulate both antigen-presenting and costimulatory molecules initiating a ‘maturation’ process. As part of this process, APCs in peripheral tissues change their chemokine receptors and initiate migration to secondary lymphoid organs where the adaptive immune response is initiated.

The strategic migration and location of DCs into T-cell areas of the secondary lymphoid organs coupled to their superior antigen-presenting capacity make them the most powerful APCs. Indeed, DCs are about 1000 times more efficient than B cells or macrophages in stimulating naive T cells. This has been shown by several experiments in which elimination of DCs prevented the initiation of antigen-specific T-cell responses. Interestingly, DCs are a heterogeneous cell population composed of different subtypes which present unique and overlapping functions. As many as six different subsets of DCs occupy the lymph nodes. Three major defined populations of DCs have been recognized in mouse spleen and humans: CD8⁺ conventional DCs (cDCs), CD11b⁺ cDCs, and plasmacytoid DCs. These subpopulations differ not only in surface phenotype but also in functional potential and localization. In this regard, cDCs are potent activators of naive T lymphocytes, as CD8^b DCs are believed to be specialized in cross-presentation of exogenous antigens. A recent study suggests that CD8⁺ and CD11b⁺ cDCs differ from each other in their intrinsic antigen-processing capacity being specialized in MHC-I and MHC-II antigen presentation, respectively. In contrast, plasmacytoid DCs are poorer activators of T cells, even after stimulation *in vitro*. They likely play a more protagonist role during innate immunity by secreting specific cytokines and chemokines, such as type 1 interferons (IFNs, an important antiviral mediator), and activation of a broad range of effector cells, such as natural killer (NK) cells. Thus, the heterogeneity inherent to DC populations significantly influences the varieties of immune responses to different pathogens, which are subsequently amplified by cross talk between the various subsets.

Major Pathways of Antigen Presentation

Although in all healthy individual’s MHC molecules play the same crucial role of antigen presentation, these molecules are highly polymorphic. There are hundreds of different alleles encoding the MHC molecules in the whole population and each individual

exhibits only a few of them. The major allelic variants of MHC are found in key amino acids forming the peptide-binding cleft. Thus, although a given MHC-I molecule can bind several different peptides; particular amino acids are preferred in certain positions of the peptide resulting in differential peptide sets for particular MHC variants. Importantly, T-cell specificity involves co-recognition of a particular antigenic peptide together with a particular MHC variant, a feature known as T-cell MHC restriction.

Like other polypeptide chains of proteins destined to arrive at the cell surface, MHC molecules are translocated to the lumen of the endoplasmic reticulum (ER) during synthesis. In this compartment, the subunits of MHC molecules are assembled together and the peptide binding groove or cleft is formed. However, MHC molecules are unstable in the absence of bound peptide. In the following sections, we will consider how MHC molecules are folded and generated peptides are bound to MHC-I or MHC-II molecules. After binding, MHC-peptide complexes travel to the cell surface where they are recognized by antigen-specific T cells. Although not discussed in this article, it should be noted that other MHC-like molecules (CD1 and MR1) also display lipid antigens and molecules from riboflavin biosynthesis, contributing to antigen presentation to T cells, especially during mycobacteria and other bacterial infections.

MHC-I Antigen Presentation

MHC-I molecules are expressed in most if not all nucleated cells. MHC-I molecules are heterodimers of a highly polymorphic α -chain (43 kDa) that binds noncovalently to β 2-microglobulin (12 kDa), which is nonpolymorphic. The α -chain contains three domains. The α 3 domain crosses the plasma membrane while the α 1 and α 2 domains constitute the antigen-binding site. The peptides that bind the MHC-I molecule are usually 8–10 amino acids long and contain key amino acids at two or three positions that anchor the peptide to the MHC pocket and are called anchor residues.

As mentioned above, the peptide-binding site of MHC molecules is formed in the ER. However, all proteins, including viral-derived antigens, are synthesized in the cytosol. Numerous studies in the last years outlined the molecular events connecting the antigen generation in the cytosol with the peptide binding to the MHC-I molecule in the ER. A highly conserved multi-catalytic proteasome complex is in part responsible for cytosolic protein degradation into small peptides. The proteasome contains 28 subunits forming a cylindrical structure composed of four rings, each of seven units. Under normal conditions, the proteasome complex exists in a constitutive form. During viral infections, IFNs released by cells of the innate immune system induce the synthesis of three different proteasome subunits, which replace their constitutive counterparts to form the immunoproteasome. This inflammatory form of the proteasome favors the production of peptides with a higher chance of MHC binding. Moreover, IFNs can also enhance the rate of proteasome peptide degradation increasing the availability of peptides and reducing their excessive cleavage. It is important to highlight that other cytosolic proteases also contribute to MHC-I peptide generation and further cleavage can occur within the ER before MHC binding. The source of peptides for MHC-I complexes still holds its secrets. Proteasome substrates may encompass de novo synthesized, mature stable, and/or defective proteins. It is believed that defective ribosomal products (DRiPs), which are proteins targeted for degradation due to premature termination or misfolding, constitute an important source of MHC-I peptides.

Peptides available in the cytosol are transported into the lumen of the ER by ATP-dependent transporters-associated antigen-processing 1 and 2 (TAP-1 and TAP-2) proteins. TAP proteins are localized in the ER membrane forming a channel through which peptides can pass. Within the ER, the newly synthesized MHC-I α -chain binds to a chaperone molecule called calnexin, which retains the incomplete MHC molecule in the ER. After binding to the β 2-microglobulin, calnexin is displaced and the emerging MHC molecule binds to a loading complex composed of the chaperone protein calreticulin, TAP, the thiol oxidoreductase Erp57, and tapasin, which bridges MHC-I molecule and TAP. The TAP molecule holds the MHC class I open and peptide receptive for competing peptides delivered by TAP. After peptide binding, the fully folded MHC-I molecule and its bound peptide are released from the complex and transported to the cell membrane. Importantly, under steady-state conditions, the MHC-I molecules in ER are in excess with respect to peptides allowing the rapid appearance of microbial peptides onto the cell surface during infection. However, since MHC-I molecules are unstable without bound peptide, they also present self-antigens under normal conditions. Because of the absence of microbial signatures, antigen presentation of self-peptides by inactivated/immature APCs leads to T-cell tolerance rather than activation. This is one of the important ways anti-self or autoimmune responses are controlled.

For several years, intracellular peptides were believed to be the only source of MHC-I molecules. However, it is now clear that exogenous proteins also have access to the cytosolic compartment and bind MHC-I in the ER. Also priming of CD8⁺ T cells by dendritic cells involves uptake of foreign antigen by the latter from cells undergoing apoptosis or necroptosis. This mechanism known as cross-presentation is important for initiating T cell responses by specialized dendritic cells. The molecular mechanism by which MHC-I molecules access exogenous peptides is of considerable interest. Different nonexclusive possibilities have been proposed, including sampling of phagosome generated peptides by MHC-I molecules, transference of ER molecules (including MHC-I and its loading complex) into phagosomes, re-entry of plasma membrane MHC-I into recycling endosomes with the subsequent peptide exchange, and finally the acquisition of peptides from other cells through GAP junctions.

MHC-II Antigen Presentation

The MHC-II molecule is composed by two noncovalently bound transmembrane glycoprotein chains, α (34 kDa) and β (29 kDa). Each chain has two domains and altogether they form a four-domain heterodimer similar to the MHC-I molecule. α 1 and β 1

domains form the peptide binding cleft resulting in a groove which is open at the ends, which is different from the MHC-I groove in which the extremes of the peptide are buried at the ends. Peptides that bind to MHC-II are larger than those that bind to MHC-I molecules, being 13–17 amino acids long or even much longer.

Since MHC-II is a surface protein, its biosynthesis is initiated in the ER. To prevent newly synthesized MHC-II molecules from binding cytosolic peptides that are abundant in the ER, its peptide-binding cleft is covered by a protein known as MHC-II-associated invariant chain (Ii) or CD74. Through a targeting sequence in its cytoplasmic domain, the Ii also directs MHC-II molecules to acidified late endosomal compartments, where Ii is cleaved leaving only the Ii pseudopeptide (CLIP) covering the peptide-binding groove. MHC-II molecules bound to CLIP cannot spontaneously bind other peptides, indicating that CLIP must be dissociated or displaced before antigenic peptide can bind.

Priming of CD4⁺ T cells by MHC-II occurs primarily in dendritic cells and B lymphocytes. Proteins that enter dendritic cells through endocytosis, are captured by Fc receptors as immune complexes or are derived from pathogens that replicate in vesicles and are degraded by endosome proteases. B cells bind antigen through their surface antibodies and then internalize it for antigen processing. These proteases become activated as the endosome pH progressively decreases. The final set of peptides available in the endosomal compartment is a result of antigen processing by several acid proteases that exist in endosomes and lysosomes. For instance, the cathepsin S is a very predominant acid protease and mice deficient in this enzyme have a compromised antigen-processing capacity. Vesicles carrying peptides fuse with the vesicles carrying MHC-II molecules, CLIP is then dissociated by the action of non-polymorphic MHC class II molecules, HLA-DM in humans and H-2 M in mice, allowing incorporation of antigenic peptides into MHC-II molecules. HLA-DM/H-2 M thus contributes to 'peptide editing' by removing weakly bound peptides and assuring that the emerging MHC-II-peptide complexes are stable enough to be scanned by CD4 T cells.

MHC-II molecules seem to be in excess and are rapidly degraded unless microbial peptides become available to fill the groove. This excess is important to permit MHC-II availability upon infection. However, during infection, APCs are exposed to both self and microbial peptides. How APCs discriminate between self and non-self represents a fundamental question in immune biology. Recent evidence suggests that the efficiency of presenting antigens from phagocytosed cargo is dependent on the presence of a TLR ligand within the cargo. Thus, TLR signaling would mark a particular phagosome for an inducible mode of maturation dictating the fate of the cargo-derived peptides and favoring their presentation by MHC-II molecules in a phagosome autonomous fashion.

Because they travel through the endocytic pathway, which can be considered a topological continuation of the extracellular space, MHC-II molecules were believed to be specialized in the presentation of exogenous antigens. However, the analysis of the MHC-II peptidome revealed many peptides of cytosolic or even nuclear origin. Autophagy or 'self-eating' explains MHC-II access to cytosolic peptides. This highly conserved pathway could be accomplished by several mechanisms including microphagy (when lysosomal invagination sequesters cytosolic components), macrophagy (when a double membrane structure encloses and isolates cytoplasmic components and eventually fuses with lysosome), and chaperone-mediated autophagy (when cytosolic proteases generate peptides that are transported into lysosomes).

Viral Subversion of Antigen Presentation

Considering the crucial role of antigen presentation for host defense, it is not surprising that many viruses have evolved maneuvers to evade or divert this process. Particularly, the essential role played by APCs in host defense to pathogens makes them an ideal target for viruses to suppress the immune response, thereby maximizing their chances of survival, replication, and transmission. Indeed, many viruses that cause major health problems are able to interfere with the ability of APCs to prime an efficient and effective antiviral immune response. In fact, many viruses have developed different mechanisms to subvert each stage of APC biology. Furthermore, with the greater understanding of antigen presentation pathways comes the discovery of novel viral immune-evasion strategies. In this section, we illustrate selective viral strategies to subvert antigen presentation by describing particular cases.

An interesting example of virus blockade of antigen presentation from very initial steps is the ability of the prototypic arenavirus lymphocytic choriomeningitis virus (LCMV), to dramatically block DC development from early hematopoietic progenitors. Fms-like tyrosine kinase 3 ligand (Flt3L) is known to induce the expansion of undifferentiated progenitors into DCs within the spleen and bone marrow (approximate 20-fold increase), both in mice and humans. In contrast, LCMV-clone (CL) – 13 that suppresses the immune response and causes a persistent infection in mice is associated with DC early progenitors that become refractory to the stimulatory effects of Flt3L.

TLRs function in APCs as an early sensor against pathogens; therefore, impairment in TLR signaling confers another selective advantage to certain infectious agents. As an example, vaccinia virus (VV) blocks TLR signaling and the subsequent maturation of APCs. Specifically, two proteins of VV suppress intracellular signaling of interleukin-1 (a potent pro-inflammatory host factor) and TLR-4.

Migration of DCs is a crucial step in initiating the adaptive immune response. Examples of viruses that have developed mechanisms to prevent migration of infected DCs to lymphoid organs are herpes simplex virus (HSV) 1 and human cytomegalovirus (HCMV). In both cases, there is an inhibition of complete DC maturation and subsequent expression of chemokine homing receptors. In addition, HCMV inhibits DC migration one step further by preventing APCs from arriving at a site of infection by producing homologs of chemokines that interfere with host pro-inflammatory chemokine gradients.

Another effective immune-evasion strategy used by viruses to disrupt APCs is the prevention of or interference with antigen-specific T-cell activation. The ability to disrupt MHC-peptide binding has evolved in many different virus species including adenovirus and human immunodeficiency virus (HIV). Herpesviruses have also evolved to block host cell antigen presentation. Some mechanisms utilized by herpesviruses to disrupt the antigen-presentation pathway include blocking peptide transport to the ER through interference with TAP proteins (HSV ICP47, HCMV US6), transport of particular MHC-I heavy chains from the ER to the cytosol where they are destroyed (HCMV US11, HCMV US2), retention of specific MHC-I heavy chains in the ER (HCMV US3, murine CMV-MCMV-m152), and disruption of T-cell recognition of MHC-I on the cell surface (MCMV m04). That viruses have independently evolved numerous mechanisms to disrupt MHC-peptide presentation indicates the effectiveness and importance of this strategy to the survival of viruses with different infectious life cycles.

Maturation of APCs results in upregulation of costimulatory molecules and expression of cytokines that enable them to stimulate naive T cells. Viruses that can impair T-cell stimulation by preventing the upregulation of costimulatory molecules include Ebola virus, Lassa fever virus (LFV), HSV-1, and HIV. Additionally, a number of viruses (hepatitis C virus (HCV), HIV, measles virus (MV), and dengue virus (DV)) are also able to inhibit interleukin (IL) – 12 production, which is often required for effective T-cell response. HCV does this through the action of its core and nonstructural protein 3 (NS3), which induces production of IL-10. DV, on the other hand, is able to inhibit IL-12 production through an IL-10 independent mechanism. In addition, compelling evidence showed that in vivo persistent infection of mice with LCMV, as well as persistent HCV infection in humans, induces IL-10 production by APCs resulting in the blunting of the CD8 T-cell response and chronic viral infection. Remarkably, antibodies blocking IL-10/IL-10R interactions correct T-cell exhaustion by restoring T-cell function, which results in purging of virus from mice persistently infected with LCMV.

Finally, a novel immunosuppressive molecule, programmed cell death-1 (PD-1), is upregulated in nonfunctional CD8 T cells during chronic infections (LCMV, HIV, HCV). Interaction of PD-1 with PD-ligands on APCs (or parenchymal cells) inhibits lymphocyte activation. It should also be noted that many cancer cells upregulate the PD-1 ligand PDL1 and inhibit T cell responses; recent immunotherapies can block this interaction with some success. Similarly, antibodies interfering with PD-1/PDL interactions also promote viral clearance from a persistently infected host.

The fact that not all viruses are able to block APC maturation does not necessarily represent a failure of the pathogen or a success for the host. A good example of this is observed following MV infection that exploits the ability of DCs to mature and migrate to lymphoid organs in response to infection. MV benefits greatly by having infected DCs home to lymphoid compartments where the infected cells are able to actively suppress T-cell proliferation (mediated through T-cell contact with surface viral glycoproteins) and also facilitate virus spread to more lymphoid cells. Therefore, the full understanding of the virus–host relationship requires not only studying the active mechanisms that viruses use to disable the immune system, but by also asking how a virus benefits by not altering a particular immune function.

Concluding Remarks

Co-evolution of certain hosts and pathogens for millions of years has resulted in a fine-tuned equilibrium that enables survival of both. Antigen presentation is one of the critical elements in this balance. While antigen presentation is an essential process for long-term effective host defense, targeting APCs represents a common maneuver of many viruses to avoid host surveillance and establish a chronic or persistent infection. A major challenge in biomedical research is to thwart microbial APC subversion to promote eradication of the pathogen. A better understanding of the mechanisms used by APC to display microbial antigens as well as the virus strategies to subvert APC functions during immune responses will provide new tools for designing novel vaccination approaches and immunotherapeutic treatments for human infectious diseases.

Defense Against Viruses and Other Genetic Parasites in Prokaryotes

Kira S Makarova, Yuri I Wolf, and Eugene V Koonin, National Center for Biotechnology Information, National Library of Medicine, Bethesda, MD, United States

© 2021 Published by Elsevier Ltd.

Introduction

Parasitism, including genetic parasitism, is a pervasive and, arguably, fundamental feature of life. The constant competitive coevolution between parasites and their hosts is the classical case of the Red Queen evolutionary dynamics and is believed to have profound consequences for the history of life on Earth. It is not surprising, therefore, that genomes of all life forms carry the deep imprint of this constant arms race. Genomes of hosts harbor numerous active and passive defense systems and mechanisms, while those of parasites are replete with systems adapted to overcome these defenses.

A genetic parasite can be defined as a non-cellular DNA or RNA-based life form, which relies on the host resources and cellular machinery to propagate. Genetic parasites include viruses, plasmids and transposable elements. These elements are typically deleterious to the host, but some of them could be only mildly so, neutral, or even beneficial to the host in some conditions. The focus of this article is to review organization and evolution of major types of defense systems that prokaryotes (bacteria and archaea) deploy against genetic parasites. However, it is important to note that many components and principles of organization of these systems are similar to those molecular systems that are involved in conflicts between cellular life forms. The latter include numerous offense systems such as polymorphic toxins and virulence factors and the defense or immunity systems counteracting these toxins.

Bacterial, archaeal and eukaryotic defense systems and mechanisms share similar organization principles ([Table 1](#)). Moreover, in full agreement with the arms race paradigm, the parasites also have an impressive arsenal of both active and passive mechanisms to overcome host defenses. Passive defense prevents the entry of a genetic parasite through the cellular membrane. Typically, viruses and plasmids use specific surface proteins (receptors) and/or cellular DNA uptake machinery to enter the cell. Therefore, these receptors or outer components of DNA uptake machinery could be either modified, preventing their recognition, or physically blocked. There are multiple ways to modify these components, including minor (mutations) and major (rearrangements, insertions, deletions) changes of the respective protein sequences and enzymatic modifications of proteins, such as (partial) proteolysis and glycosylation. Receptor blocking includes protein-protein interactions, glycosylation or occlusion of the receptor by glycan capsule or extracellular matrix. In addition, some bacteria deploy decoy outer membrane vesicles that contain receptors and therefore mislead phages into binding to them instead of the receptors on the cell surface. In eukaryotes, analogous mechanisms of passive protection are also known and some of them involve activity of domesticated viruses which express proteins, blocking cognate receptor and preventing its binding by other viruses.

Active immunity mechanisms typically involve intracellular response to foreign nucleic acid or general stress induced by parasite activity inside the cell. These mechanisms can be roughly classified into specific immunity and non-specific response causing cell suicide (programmed cell death, PCD) or dormancy ([Table 1](#)). The latter mechanisms include numerous toxin-antitoxin (TA) and abortive infection (ABI) systems in prokaryotes discussed below and elaborate apoptosis mechanisms centered around caspase family proteases in eukaryotes. These systems could be also activated by other causes, such as DNA or protein damage. Specific immunity systems are classified into innate immunity and adaptive immunity and depend on the ability to distinguish self versus nonself ([Table 1](#)). Adaptive immunity systems differ from innate immunity in that they develop a highly specific immune response during organism exposure to a parasite; typically, adaptive immunity is more efficient than innate immunity. In prokaryotes, both innate immunity and adaptive immunity operate on the level of nucleic acids recognition and targeting. In eukaryotes, much of innate immunity and all known adaptive immunity mechanisms are based on protein-protein recognition. The only known defense system that is common between prokaryotes and eukaryotes is centered on PIWI domain (nuclease of RNase H fold) containing proteins known as Argonats (AGO). RNA-guided AGOs play key roles in the multiple pathways of RNA interference which protect eukaryotes against RNA viruses; separate branches of the RNA interference network evolved to regulate translation of eukaryotic mRNAs. In contrast, prokaryotic AGOs are either RNA- or ssDNA-guided and so far have been shown to target, primarily, foreign DNA. Several other prominent components of defense systems are also shared between prokaryotes and eukaryotes, but their roles in defense in either prokaryotes or eukaryotes are not well understood. For example, the bacteria and archaea encode numerous immunoglobulin (IG) domains and leucine-rich repeats (LRR) as well as caspase family proteases that can be tentatively predicted to function in defense, but their actual functions remain to be studied experimentally. Conversely, the roles of many eukaryotic nucleases derived from bacterial TA and ABI system remain unclear or are unrelated to defense. Thus, further research might identify more common traits in the organization of defense pathways in all three domains of life.

Table 1 Classification of defense systems and comparison between prokaryotes and eukaryotes

Active response			Passive resistance
Self-nonsel self differentiating			
Adaptive immunity	Innate Immunity	Programmed cell death or dormancy	Avoidance
Bacteria and archaea			
CRISPR-Cas	RM, DND, DPD, PGL/BREX, DISARM, <u>PIWI</u>	TA, ABI	Receptor mutations, Receptor blocking, Decoy OMV
Eukaryotes			
IG immunity, LRR immunity	<u>PIWI</u> , Interferon	Caspase pathways	Receptor mutations, Receptor blocking

Abbreviations: ABI, abortive infection systems; BREX, bacteriophage exclusion system; Cas, CRISPR-associated proteins; CRISPR, clustered regularly interspaced short palindromic repeats; DISARM, defense island system associated with restriction modification; DND, DNA phosphorotiation and degradation system; DPD, 7-deazapurine in DNA system; IG, immunoglobulin; LRR, leucine rich repeats; OMV, outer membrane vesicles; PIWI, argonaute or related RNA or DNA interference systems; RM, restriction modification systems; TA, toxin-antitoxin systems.

Note: The only defense system shared between prokaryotes and eukaryotes, centered around the Argonaute (PIWI) proteins, is underlined.

Classification and Diversity of Defense Systems

Toxins-Antitoxins: PCD or Dormancy Systems

All PCD systems harbor toxic components that either kill the host cell or cause major disruption in house-keeping pathways, triggering reversible cell dormancy. These toxins might be either inactivated or suppressed by a dedicated antitoxin molecule and/or repressed/de-repressed by a dedicated transcriptional regulator. Although it is common to refer to two PCD systems in bacteria and archaea, TA and ABI, the distinction between these is fuzzy. TA modules are most abundant defense/stress response systems in archaea and bacteria. Currently, TA systems are classified into 6 types depending on the nature of the toxin and antitoxin, and on the mode of their interaction. Type I systems consist of protein toxin, typically, a small pore-forming membrane protein, and an RNA antitoxin. The antitoxin RNA hybridizes with the toxin mRNA and prevents its translation. In type II TA, both components are proteins. The antitoxin in these systems often has a dual function. In addition to directly interacting with the toxin and blocking its activity, the antitoxin often contain a DNA-binding domain and doubles as a transcriptional regulator. Most known type II toxins are RNases of 6 distinct structural folds, namely, RelE/Txe (RelE-like fold), MazF/Kid/PemK (SH3-like fold), PIN (PIN-like fold), VapC (ferredoxin-like fold), HicA (dsRNA-binding-like) and HEPN (four-helical up-and-down bundle, named for “higher eukaryotes and prokaryotes nucleotide-binding domain”), which all target host RNAs. A minority of toxins have other toxicity mechanisms. New mechanisms of toxicity continue to be discovered and include most recently characterized acetyltransferases TacT, AtaT, ItaT and related toxins that acetylate amino groups of tRNAs, DarT which ADP-ribosylates single-stranded DNA, and RES domain toxins that either degrade NAD or act as mono-ADP-ribosyl-transferases modifying phosphoribosyl pyrophosphate synthetase, an essential enzyme of nucleotide biosynthesis. In type III systems, such as ToxIN and CptIN, RNA antitoxins interact directly with MazF-like RNase toxins. The ToxIN system is involved in abortive infection mechanism of phage exclusion and was previously discovered and described as ABI system AbiQ in *Lactococcus lactis* plasmid pSRQ900. In the type IV CbtA/CbeA system, toxin CbtA inhibits cell division by targeting FtsZ and MreB whereas antitoxin CbeA protects these proteins from the interaction with the toxin but, in contrast to most of the TA systems, does not bind the toxin. In type V system, GhoT is a membrane protein whose mRNA might be cleaved by the antitoxin GhoS, an endoribonuclease of the ferredoxin fold. Type VI systems consist of the toxin SocB which blocks replication by binding DnaN protein and antitoxin SocA that promotes degradation of the toxin by ClpXP proteases. Recently, the first all-RNA toxin-antitoxin system SdsR/RyeA has been reported. The mechanism behind the toxicity is repression of *yhcB* gene coding for an uncharacterized membrane protein of DUF1043 family. The simple organization of TA systems and several distinct features of each type provide for prediction of new TA variants using comparative genomic and sequence analysis methods. Many new TA systems have been so predicted but not yet explored experimentally, and undoubtedly, many more remain to be discovered.

So far there have been no consistent attempt to classify ABI system because of their enormous diversity, and therefore, these systems are currently treated as one loose group based on the phage exclusion effect of their expression. Moreover, most of them were identified in a single bacterial group, lactococci, so the potential diversity of these systems clearly is far from being exhausted. Many ABI systems consist of two components which is compatible with their classification as TA systems, whereas most of the rest consist of a single gene. Three TA/ABI systems have been characterized experimentally, namely, the AbiQ family of type III TA systems, AbiE family of type IV TA systems that consists of the nucleotidyltransferase toxin AbiEii and the non-interacting antitoxin AbiEi which represses expression of both genes. For the overwhelming majority of the ABI systems, the molecular mechanism is not yet known.

Self Versus Nonself Recognition Innate Immunity Systems

The simplest innate immunity system is the prokaryotic Argonaute (pAGO). pAGOs can use short RNA or ssDNA guides to target foreign DNA in a sequence-specific manner. However, some pAGOs can cleave DNA in a guide-independent mode. The latter activity might provide ssDNA guides for the guide-dependent DNA cleavage. The mechanism of self versus nonself discrimination during target loading is not understood yet. Sequence comparison, in agreement with phylogenetic analysis, divides pAGOs into two major groups that are known as long and short pAGOs depending on the domain organization. Long pAGOs have the same domain composition as eukaryotic AGOs and are comprised of four distinct regions: N-terminal region involved in target-guide duplex positioning, PAZ (PIWI-Argonaute-Zwille) domain responsible for binding 3' guide-RNA binding, MID (middle) domain involved in 5'-guide binding and catalytic PIWI domain of RNase H fold. Short pAGOs contain only the MID and PIWI domains. All short pAGOs and several long pAGOs are predicted to be inactivated because of substitutions in catalytic sites in the PIWI domain. Inactivated long pAGOs are typically associated with different nucleases which might function as effectors, possibly, interacting with pAGO and cleaving DNA. The key feature of short pAGO systems is the presence of the yet uncharacterized APAZ ("analog of PAZ" which, however, displays similarity to the N-terminal domain of AGO) domain-containing protein encoded in the same operon. Putative effector proteins, such as SIR2 (sirtuin) deacetylases or nucleotide-binding TIR (Toll/interleukin-1 receptor) domains, are also encoded in the same operon or fused to the APAZ domain. Their exact functions remain unclear. Another bacterial protein family (PF13032 RNaseH_pPIWI_RE, formerly known as DUF3893) distantly related to pAGOs is linked to the helicase DinG and a nuclease of the PD-DEXK family, and is proposed to function as an RNA-dependent restriction system. So far none of the RNaseH_pPIWI_RE proteins has been studied experimentally.

The innate immunity systems we describe next depend on the DNA modification status for self versus nonself discrimination (Fig. 1). Restriction Modification (RM) systems are by far the best-studied because, from the time of their discovery, they are extensively being used in molecular biology as an essential tool for sequence-specific DNA cleavage. The RM systems are currently classified into four types based on differences in their gene organization, target recognition and location of cleavage sites. Type I includes classic RM systems that consist of three genes with four distinct functions, namely, HsdR (R), endonuclease fused to a helicase or DNA translocase domain (T), HsdM (M), methyltransferase, and HsdS (S), the specificity subunit containing at least one target recognition domain (TRD) that determines sequence specificity (Fig. 1). These proteins form hetero-oligomeric complexes that cleave DNA away from the recognition site. The key difference between type I and type II is the absence of the helicase (translocase) domain in the latter. Many of the type I enzymes are homodimeric or monomeric with all the functionalities (R, M, S) encoded within the same polypeptide. The absence of DNA translocases suggests that the DNA cleavage occurs within the recognition site or close to it. The extremely numerous and abundant Type II RM consist of two genes, SR and SM (Fig. 1). However, domain architectures of these systems are variable. The RM systems of Type IIP (where P stands for "palindromes"), such as EcoRI, contain both S and R domains within the same polypeptide and cleave palindromic sites which makes them particularly well-suited for recombinant DNA technology. Thus, several thousand of these enzymes have been characterized experimentally, many of them in detail. Type III RM systems, such as, for example, EcoP1, typically have all four functionalities combined in two proteins: Mod, containing M and S domains, and Res, containing R and T domains. Type IV is the only variety of RM systems that lack the M component because these enzymes cleave DNA modified by phage methylases. McrBC from *Escherichia coli* K12 is the best studied representative of this RM type.

Two additional microbial defense systems rely on DNA methylation for self versus nonself discrimination; these systems appear to be more complex than the typical RM, and their investigation has started only relatively recently. One of these is BREX (Bacteriophage Exclusion), which methylates bacterial DNA, providing for discrimination between the host and phage genomes, and blocks phage replication. BREX shares several key components with the PGL (phage growth limitation) system. PGL had been originally suggested to function as "reverse RM" because in *Streptomyces coelicolor* this system provides resistance only during the subsequent rounds of infection by the same phages, suggesting that phage DNA is tagged for recognition during the first round of replication making the phage susceptible to PGL later. However, at least some of the BREX systems act in a "direct" way analogously to RM systems and provide phage protection during the first round of infection. There are three key, essential components in these systems: PglX, a methylase homologous to HsdM component of type I RM systems, PglZ, an alkaline phosphatase domain containing protein, and BrxC/PglY, an ATPase domain containing protein (Fig. 1). No nuclease domain was identified in these proteins which is in line with the absence of experimental evidence of DNA cleavage. Thus, the phage restriction mechanism remains to be clarified. Based on PglZ family phylogeny and gene neighborhood analysis, BREX system is divided into 6 subtypes, one of which corresponds to PGL. Apart from the conserved core, each of these subtypes have additional genes. BrxA, a protein structurally similar to the recognition domains of RM systems, BrxB, an uncharacterized protein of DUF1788 family, BrxL, a Lon family protease, BrxW, a serine-threonine protein kinase, and BrxH, a helicase, are among the most common ancillary genes (Fig. 1). However, their role in BREX function remains enigmatic.

The recently identified DISARM (defense island system associated with restriction modification) system has been shown to methylate host DNA and restrict invading dsDNA phages. There are two types of DISARM systems that share three proteins: DrmA, a COG1205 helicase, DrmB, a DUF1998 domain containing protein previously noticed to be fused to a COG1205 helicase, and DrmC, a phospholipase D (PLD) family nuclease. Two common associated genes differ between the two types of DISARM. DISARM I loci encode an additional helicase DrmD (COG0553) and an adenine methylase DrmMI that appears to be a derivative of type IIG RM systems, with the nuclease domain likely inactivated. DISARM II loci encode the cytosine methylase DrmMII and an uncharacterized protein DrmE, an inactivated helicase containing C-terminal helix-turn-helix DNA-binding domain. The

DISARM II system has been studied experimentally and cytosine methylation by DrmMII has been shown. However, it has been also demonstrated that some phages that lack methylation motifs are nevertheless restricted by DISARM II system, suggesting that the protection mechanism could be more complex. This is in line with the observation that the PLD family nuclease is not essential for the protection.

Currently, two innate immunity systems are known that employ DNA modifications other than methylation for self versus nonself discrimination. The DPD (for 7-deazapurine in DNA) system inserts 7-deazaguanine derivatives and restricts unmodified DNA. Typically, the DPD system is encoded in two gene modules that include, respectively, the enzymes of the 7-deazapurine biosynthesis pathway and proteins involved in the recognition and restriction of unmodified DNA. The latter module typically encodes 10 proteins (DpdABCDEFHIJK) but in some bacteria shows more variability, so it is presently unclear which genes are essential for the system functions and which are ancillary. The key gene in the cluster is DpdA/TgtA5, the queuine/archaeosine tRNA-ribosyltransferase family enzyme, which exchanges guanine for the modified base in DNA. In addition, the *dpd* genes encode three distinct helicases, an AAA ATPase, a DNA binding protein containing ParB family NTPase domain, a PLD nuclease and a few uncharacterized proteins (Fig. 1). The PLD nuclease is strongly linked to the COG1205 helicase which is fused to a DUF1998 domain containing protein. The same genes are present in DISARM systems (Fig. 1). The details of the restriction mechanism by the DPD system are not understood yet.

The second system, DND (for DNA degradation), also often referred as DPT (DNA phosphorotioation) system, replaces a nonbridging oxygen in the DNA backbone with sulfur and cleaves unmodified DNA. The DND system consists of two modules: DndABCDE proteins that are essential for DNA modification, and DndFGH proteins that are required for restriction. DndA/IscS, cysteine desulfurase and DndC/CysH, ATP pyrophosphatase related to phosphoadenosine phosphosulfate reductase, appear to be the enzymes that catalyze oxygen replacement with sulfur. Other components, namely, DndB and DndE, two distinct DNA-binding proteins, and DndD, an ATPase of the Mre11/Rad50 family, are likely responsible for specific site targeting and providing energy for sulfur incorporation. It has been demonstrated that DndACDE proteins form a complex and DndB is involved in transcriptional regulation. Although the restriction mechanism remains obscure, sequence analysis suggests that DndH, which contains a PD-DExK endonuclease domain, cleaves unmodified DNA. Other components, DndF, an ATPase and DndG, another DNA binding protein, are also essential for restriction. Interestingly, only approximately half of the genomes that encode DNA phosphorotioation module, also have the DndHGF restriction module, suggesting that alternative restriction mechanisms might be coupled with the phosphorotioation module. Indeed, it has been recently shown that HNH nuclease associated with type IV RM systems cleaves both methylated and phosphorotioated DNA.

CRISPR-Cas – The Adaptive Immunity System

CRISPR-Cas (CRISPR – Clustered Regularly Interspaced Short Palindromic Repeats; Cas – CRISPR associated proteins) is the only known adaptive immunity system in bacteria and archaea. During a (failed) virus infection, short fragments of virus DNA are inserted into a CRISPR array becoming unique spacers that separate the repeats. The array is transcribed, and the primary transcript is cleaved by a dedicated complex of Cas proteins, giving rise to crRNAs (CRISPR RNAs) which serve as guides for the effector machinery of the system. The memory of virus encounters is stored in the genome and is inherited by the progeny of the “vaccinated” bacterium or archaeon, so that the CRISPR-Cas systems embody Lamarckian-type evolution. The typical length of a spacer is about 40 nt, so that CRISPR-cas can be programmed to target unique sites even within a large eukaryotic genome. This property quickly made the CRISPR-Cas system the main tool in the new generation of genome editing techniques and other biotechnological applications, and triggered extensive research on all aspects of the molecular mechanisms, genetic organization, structure and evolution of this system. Numerous up to date reviews discuss different topics of CRISPR-Cas biology and genetic engineering applications (see Further Reading list), so here we briefly review only general features of CRISPR-Cas systems organization and their current classification.

Due to the remarkable diversity of the CRISPR-Cas systems, their classification is hierarchical and is based on a multipronged approach. Such features as gene composition, phylogeny of CRISPR-Cas signature gene *cas1*, sequence and structural similarity of

Fig. 1 Genetic organization of self vs. nonself discriminating innate immunity systems. Abbreviated classification and the type of the system are indicated on the left in green font. Abbreviation of the systems are the same as in the Table 1. DNA modification type abbreviations: m6A – Methylation of the adenosine base at the nitrogen-6 position; m5C – Methylation of the C-5 carbon of cytosine. Arrows schematically indicate the most frequent genes associated with each system. Above an arrow the gene name is indicated if known. Protein family and/or brief enzyme description are indicated below the arrow for less characterized systems. Four typical functionalities are indicated inside the arrows as follows: R – Endonuclease domain, M – Modification domain, S – Recognition or specificity domain, T – DNA translocation domain (typically a helicase). Homologous domain or proteins are shown by the same color and indicate a protein family sharing phenomenon between different systems. Black rectangle indicates DUF1998 (small metal-binding domain), which is typically a C-terminal domain of a larger protein of unknown function often fused to COG1205 helicase. Question mark indicates uncertainty of functional assignment in the absence of experimental data. Dashed line separates a few recently identified defense systems which have some components shared with known self-nonself recognitions systems, but their mechanism is yet to be characterized. COG (clusters of orthologous groups) and DUF (domain of unknown function) correspond to protein families from COG and PFAM databases respectively. Other abbreviations: PAPS, phosphoadenosine phosphosulfate; HTH, helix turn helix domain; PLD (phospholipase D), PD-(D/E)xK – Nucleases from respective superfamilies.

Fig. 2 Core *cas* genes and modular organization of CRISPR-Cas systems. (A). Class 1 and Class 2 CRISPR-Cas systems and 13 core gene families. General architectures of class 1 (multiprotein effector complexes) and class 2 (single-protein effectors) CRISPR-Cas systems is schematically shown. Genes are shown as arrows. Homologous genes are shown by the same color. Gene names follow the current nomenclature and classification. Abbreviation: *tracrRNA*, transactivating crRNA (CRISPR RNA). (B). The middle panel shows the principal building blocks of CRISPR-Cas system types. An asterisk indicates the putative small subunit that might be fused to the large subunit in several Type I subtypes. The dash next to the CARF and HEPN domains indicates that other unknown sensor and effector domains can be involved in the signaling pathway. Dispensable genes are indicated by the dashed outline. The figure is modified from Koonin, E.V., Makarova, K.S., 2019. Origins and evolution of CRISPR-Cas systems. *Philosophical Transactions of the Royal Society B* 374 (1772), 20180087.

effector proteins and complexes are all taken into account. The CRISPR-Cas systems are divided into two classes (Fig. 2(A)). Class 1 includes the variants with multi-subunit effector complexes whereas systems with a single-protein effector (SPE) belong to Class 2. Both Class 1 and Class 2 system effector genes (effector modules) are linked to a CRISPR array containing a variable number of repeats and spacers, and an adaptation module typically consisting of two genes, *cas1* and *cas2* (Fig. 2(B)). Several adaptation modules include an additional gene, *cas4*. *Cas4* protein interacts with *Cas1* and *Cas2* complex and defines several features of spacers that are integrated into CRISPR loci. Class 1 and Class 2 systems are further classified into 6 types and more than 20 subtypes (Fig. 2(B)). A signature protein family is assigned to each subtype. These signature families are *Cas3* (helicase-nuclease), *Cas9* (SPE), *Cas10* (large subunit of effector complex), *Csf1* (large subunit of effector complex), *Cas12* (SPE), and *Cas13* (SPE) for types I, II, III, IV, V and VI, respectively. Despite the extremely low or undetectable sequence similarity between protein subunits, type I, III and IV systems share common principles of effector complex organization and are apparently homologous. Typically, effector complexes of these systems contain one large subunit (*Cas8*, *Cas10* and *Csf1* respectively), several small subunits of the *Cas11* group (which sometimes are fused to large subunits), one *Cas5* family protein and several *Cas7* family proteins (Fig. 2(B)). The *Cas5* subunit binds the 5' handle of the crRNA and interacts with the large subunit. Small subunits interact with the crRNA backbone bound to *Cas7*. The *Cas6* protein is an RNase which is required for crRNA maturation. Type I systems target double-stranded DNA, and the *Cas3* helicase that is typically fused to an HD family nuclease is responsible for the cleavage. Type III systems cleave both DNA, via an HD nuclease that is typically fused to the *Cas10* protein, and RNA via the *Cas7* RNase. Type IV systems are poorly characterized but are predicted not to be active in interference, and accordingly, to function via alternative mechanisms. Multiple additional genes that either help with some steps of CRISPR-Cas function or are involved in regulation and signal transduction constitute the ancillary module and signal transduction modules (Fig. 2(B)). So far only type III systems are known to employ an essential signal transduction pathway in which *Cas10* catalyzes the synthesis of a cyclic oligoadenylate, a signaling molecule that activates the HEPN domain of an ancillary *Cas* protein, a non-specific RNase. This RNase can both degrade viral transcripts and cause PCD or dormancy. To prevent the latter, there are dedicated nucleases that cleave the signaling molecule.

Unlike Class 1, all three distinct types of Class 2 have independent origins although type II and type V share a common domain of RNase H fold (RuvC-like) which is involved in ssDNA nicking. The second domain, HNH family nuclease, in type II SPE (*Cas9*) cleaves the second DNA strand, whereas in type V systems the RuvC like domain cleaves both strands. The crRNA processing in

type II and several type V subtypes requires additional host-encoded RNase III and an additional RNA molecule, known as tracrRNA (trans-activating crRNA), that is encoded in the vicinity of the CRISPR-cas loci and apparently evolved by duplication and divergence of a repeat. The tracrRNA remains bound to the corresponding SPE. Several other type V SPEs do not require tracrRNA but contain a dedicated domain involved in pre-crRNA processing. Type V currently includes the largest number of experimentally characterized and predicted subtypes, in particular, small SPEs that are thought to be evolutionary intermediates between non-autonomous transposons encoding RuvC-like domain containing TnpB proteins, but also large, elaborate SPEs such as Cas12a,b,c. Type VI is an RNA targeting system. Cas13, the SPEs of type VI, contains two HEPN domains, involved in RNA cleavage and a domain required for pre-crRNA processing. Once activated by the RNA target recognition, Cas13a becomes a non-specific RNase and might cause dormancy or cell death.

Unclassified Defense Systems

For a number of defense systems too little is known to confidently classify them into any of the categories described above (Table 1). Some of these systems have been experimentally shown to contribute to defense whereas other are only predicted *in silico*. In particular, a dedicated effort on prediction and validation of defense mechanisms has led to the identification of 9 new defense systems. Some of these might be novel self versus nonself recognition systems because they share some components with known defense systems of this type (Fig. 1). For example, all three types of Druantia system (named after a deity from Gallic mythology) contain a COG1205 helicase fused to DUF1998, which is similar to the helicases present in DISARM and DPD systems. Druantia type II system has a DNA methylase of the DCM family similarly to the DISARM II system. Two-component systems consisting of a nuclease and helicase or ABC ATPase, the Hachiman (after Japanese syncretic deity of archery and war) and Lamassu (after Assyrian protective deity) respectively, could be analogs of type IV RM systems (Fig. 1), but currently their mechanisms remain unclear.

Many other defense systems were described by comparative genomics and sequence analysis but remain uncharacterized experimentally. For instance, ATPases of the MORC family are often encoded in the same gene neighborhoods with helicases, nucleases and methyltransferases and might be core proteins of a new class of self versus nonself recognition systems. A distinct subfamily of UvrD-like helicases is linked to Dcm methylases and Cas4-like nucleases and also could be predicted to represent a distinct defense machinery that involves self versus nonself discrimination. Many putative ABI systems were predicted by analysis of defense islands and gene neighborhood of HEPN RNases. Experimental study of these and other predicted defense systems should reveal many new molecular mechanisms of defense.

Genomic Organization and Evolution of Defense Systems

Defense Islands and a Tight Link between Defense and Mobilome Genes

Defense genes and typical mobilome components, such as viral, plasmid and transposon genes, show statistically significant clustering in genomic islands. Such islands can be roughly defined as genomic regions flanked by housekeeping genes and containing at least one known defense gene present. Other defense and mobilome genes and uncharacterized genes, if present in the respective genome region, are included in the island. This observation led to the prediction of many new defense genes and systems that are over-represented in such islands. Furthermore, the so-called cargo of many mobile elements includes diverse defense genes that could counter host defense, contribute to competition between mobile elements or serve as addition modules. Defense genes are especially common in some groups of mobile elements, such as Tn7-like transposons and integrative and conjugative elements (ICEs) but, surprisingly, are relatively rare in plasmids and viruses (Fig. 3). It can be argued that all defense genes belong to regions of genome plasticity and, at some point in their evolution, could have been associated with MGE. Not surprisingly, defense genes are more prone to horizontal gene transfer (HGT) than any other functional class of microbial genes except for the mobilome itself, and multiple examples of recent acquisition of defense islands can be observed when closely related genomes are compared.

Remarkably, some of the defense systems were apparently recruited by MGEs to facilitate transposition. The most prominent example is the association of Tn7-like transposons with CRISPR-Cas systems that are competent for precrRNA

Fig. 3 Tn7 cargo genes and recruited CRISPR-Cas systems. (A). Related Tn7 loci linked to CRISPR-Cas system I-F variant. For comparison a related Tn7 locus from *Vibrio parahaemolyticus* S023 without I-F system is shown. (B). Related Tn7 loci linked to CRISPR-Cas system V-U5 type. For each locus, species name, genome accession number and nucleotide coordinates are indicated. The genes of a representative locus are shown by blocked arrows with the scale roughly proportional to gene length and the direction of gene transcription. Genes are color-coded according to the functional groups explained in the inset below. Gene product names are indicated if known, otherwise abbreviated protein family description is provided below or above the respective arrows. see Fig. 1 for innate immunity systems gene names. Abbreviations: dcd, dCTP deaminatase; RT, reverse transcriptase; SLATT, membrane protein frequently associated with immunity systems; TPR, tetratricopeptide repeats containing protein; CHAT, caspase family protease; HTH, helix turn helix; WYL, transcriptional regulator of respective family; Znf, zinc finger domain containing protein; DDE, transposase of respective superfamily; OLD, ATP-dependent DNase of respective family; GIY-YIG, HNH, and PD-D/ExK are distinct DNases families; BECR and HEPN are PCD RNase families.

processing and target binding but not for DNA cleavage that is required for interference. Such CRISPR-Cas systems are hypothesized to guide Tn7 transposition according to the spacer matches which differ from the typical attachment sites recognized by the standard Tn7 transposition machinery. Fig. 3 shows gene organization of closely related Tn7-like elements associated with either CRISPR-Cas I-F (Fig. 3(A)) or V-U5 (Fig. 3(B)) systems but carrying different defense genes as a cargo. Some MGE mobilization genes have been also recruited by some defense systems. For instance, *cas1*, the signature gene of CRISPR-Cas system, likely originated from a distinct group of self-replicating MGEs called casposons and RAG1, the key enzyme of V(D)J recombination of the Ig-based adaptive immunity system in vertebrates, is derived from a eukaryotic transposon of the Transib family.

Gene and Domain Shuffling and Sharing

In addition to being HGT attractors, defense systems and islands are hot spots for non-homologous recombination. This phenomenon is well-studied for the type I RM systems and is often referred to as phase variation. The XerC-like recombinase IvrR is responsible for shuffling between the target recognition domains of the *hdsS* genes, often an *ivrR* gene, and either inverted or direct repeats. Another common mechanism mediating phase variation is DNA polymerase slippage that occurs in simple sequence repeat regions in the TRD region of the Res subunit of type III RM systems. Most likely, these or mechanistically similar processes are also involved in shuffling of domains, individual genes and gene modules in other defense systems. The described examples include restriction endonuclease domain shuffling in RM systems, switching between toxin and antitoxin in toxin-antitoxin systems and effector module shuffling in CRISPR-Cas systems.

Gene sharing is a less thoroughly understood phenomenon. It has been noticed that some superfamily II helicases, especially, COG1205 and COG0553, and ParB family proteins are abundant in defense islands but seemingly do not belong to a single conserved gene neighborhood. Fig. 1 shows that COG1205 helicase and the accompanying DUF1998 domain containing protein belong to core genes sets in DISARM, DPD and Druantia systems. The PLD domain containing nuclease, often encoded next to the COG1205 helicase and the DUF1998 protein, is present in both DISARM and DPD. Despite this link between COG1205 helicase and PLD nuclease in DISARM system, the former is essential for the protection from the phage infection, whereas the latter is not. The COG1205 helicase is also essential in type I Druantia system along with other four genes. Thus, this helicase appears to be an integral component of some defense systems and an ancillary gene in others. Further research is needed to determine whether these genes are essential in other systems and to decipher their specific roles.

Association of Defense Systems With Programmed Cell Death Components

Sequence and gene neighborhood analyzes have identified many domains and genes homologous to RNase toxins of TA and ABI systems in the neighborhoods of RM, CRISPR and other defense systems (Fig. 4). Many of these RNases belong to the HEPN domain superfamily. Only for a few of them, the role in defense is at least partially characterized. The best-studied example is the association of *prnC* anticodon nuclease gene with the type IC RM system. The PrrC proteins contains a HEPN domain and contributes to the phage T4 exclusion mechanism. Inactive PrrC is a subunit of the HsdSMR complex, but it can be allosterically activated by increased levels of dTTP or by the small anti-restriction peptide encoded by the T4 phage. Activated PrrC cleaves the anticodon of tRNA^{lys}. Phage T4 encodes an RNA repair system that consists of the Pnl and Rnl1 proteins and can reverse the damage inflicted by PrrC.

The second example of the defense-PCD association involves another HEPN domain containing protein that is associated with many type III CRISPR-Cas systems. In these proteins, the HEPN domain is fused to a CARF (CRISPR-associated Rossmann fold) domain and is allosterically activated through the binding of a cyclic oligoadenylate that synthesized by the Cas10 protein by the CARF domain. Once activated, HEPN cleaves RNA in a non-specific manner. This activation is reversible because cyclic oligoadenylate messengers are hydrolyzed by dedicated nucleases. Furthermore, as mentioned above, effector proteins of type VI CRISPR-Cas systems become non-specific RNases upon binding the crRNA and the cognate RNA target.

There are two hypotheses explaining the coupling of defense and PCD systems: first, dormancy induction allows the host to “buy time” for the activation of other defense systems, in particular, adaptive immunity; second, dormancy or ‘altruistic’ suicide can be the ‘last resort’ measure to prevent viral spread if other immunity mechanisms fail.

Fig. 4 HEPN domain containing PCD/dormancy RNases linked to various defense systems. The genes are shown as colored arrows. Gene names (if known) are indicated below respective arrows. Colors correspond to distinct defense system groups, which are circles by dashed lines. Multidomain proteins are colored blue, known domains are indicated below the arrows. The HEPN domain is shown by a light green shape with a red outline. Distinct families of HEPN superfamily are indicated on the right for abortive infection systems and below the respective shapes in red font for other systems according to Anantharaman *et al.* (see Further Reading list). For each HEPN domain containing protein locus tag of respective protein is provided. The only other PCD related RNase of RelE family is shown by purple shape with red outline. Abbreviations: HEPN, higher eukaryotes and prokaryotes nucleotide-binding domain, predicted endoribonuclease; MNT, minimal nucleotidyltransferase; HNH, PD-(D/E)xK, DEDD are nucleases from respective superfamilies. RM and CRISPR-Cas gene names and types follow current nomenclature and classification.

Concluding Remarks

Despite the notable progress during the last decades, many aspects of the function, distribution and evolution of prokaryotic defense systems remain poorly understood. One of the deepest mysteries is the enormous variety of defense systems, both across the prokaryotic world and within most individual genomes. At least for self versus nonself recognizing systems, the need to recognize diverse signals could be a plausible explanation (case in point: RM systems) although the existence of separate recognition modules might mitigate this demand. The enormous abundance of PCD/dormancy systems (up to hundreds of TA and ABI modules in a single genome) suggests important roles of processes other than selection for the benefit of the host in the evolutionary dynamics of these systems. Carrying such a large number and variety of PCD/dormancy modules poses a problem for the host cell, namely, the need for regulation that is robust to adversarial tampering but has a low enough spontaneous trigger rate to preclude excessive burdening for the host. Currently, there is scant information about the regulation of TA systems except for the notion that they are upregulated by general stress and DNA damage pathways. It appears likely that the enormous abundance and wide spread of defense systems including those that mediate PCD in the prokaryotic world is, in large part, due to the fact that they themselves behave as mobile elements. The strong link between many innate immunity systems and PCD, especially, through the HEPN superfamily of RNases, clearly points to functional coupling. The mechanisms of such coupling are a major area of future research.

A notable feature of microbial defense systems is domain sharing. In particular, helicase domains are commonly shared and often essential components of these systems. An interesting possibility is that these DNA-dependent ATPases act as translocases rather than helicases, facilitating genome scanning and transport of the defense module along the DNA. This hypothesis remains to be tested experimentally.

Finally, it is important to note that a large part of the toolbox of modern molecular biology and biotechnology consists of components of microbial defense systems, in particular, those that discriminate between self and nonself, namely, RM and CRISPR-Cas. Their ability to recognize specific signals in the genome and to deliver the effector machinery to the targeted loci proved invaluable for genome editing methods. The future research in microbial defense can be expected to bring forth new discoveries and, with them, new tools for practical use.

Defective-Interfering Viruses

L Roux, University of Geneva Medical School, Geneva, Switzerland

© 2008 Elsevier Ltd. All rights reserved

This is a reproduction of L. Roux, Defective-Interfering Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00379-4.

History

In 1943, Henle and Henle reported the decreased infectivity for mice of influenza virus stocks obtained after a series of undiluted passages in embryonated chicken eggs. In the early 1950s, von Magnus showed that such undiluted passages generate incomplete virus particles capable of limiting the growth of infectious virus (hence exhibiting interference). This first characterization was soon followed by similar reports by Mims, on the one hand, and Cooper and Bellet, on the other, dealing respectively with Rift Valley fever virus and vesicular stomatitis virus (VSV). In the late 1950s, Cooper and Bellet went so far as to assign interference to sedimentable particles, but failed to identify them as antigenically related to VSV. From the mid-1960s on, the characterization of other positive- and negative-stranded RNA virus defective particles continued. In 1970, a review by A. Huang and D. Baltimore set the basic definition of defective interfering (DI) particles and emphasized their widespread occurrence. Since then, DI particles have been described for almost all the known DNA and RNA viruses, including plant and even fungal viruses.

Structure

DI particles have the same protein composition as their homologous nondefective 'parents', often called St. However, they differ from the St particles in the primary structure of their genome. As emphasized later, DI genomes lack part of the genetic information. They may or may not serve as coding sequences. However, they always conserve the *cis*-sequences needed for replication initiation (origins of replication), sometimes present in more than one copy, and sequences involved in encapsidation. Foreign sequences can also be inserted. DI particles can sometimes be separated from St particles on the basis of size, when the size of the particle closely corresponds to the size of the genome (for instance rhabdovirus), or on the basis of particle density differences (changes in nucleic acid to protein ratios). Often, however, only viral stocks enriched in DI particles are available owing to the size heterogeneity of the virus particles.

Generation of DI Genomes

DI DNAs very likely arise from various recombinational events not necessarily linked to genome replication, and which result in deletion, tandem duplication, insertion of host DNA, and polymerization of small monomer sequences. DI RNAs have been proposed to arise almost exclusively during genome replication by a mechanism of 'leaping polymerase' consisting of polymerase stop/fall-off or slippage/reinitiation events (Fig. 1). In this model the replicase complex moves with the nascent RNA still attached to it. Depending on where reinitiation takes place, and on the number and the direction of the leaps, the resulting molecules can be of the copy-back type, with more or less intramolecular inverted complementary sequences (a), of the internal deletion type (b), and of the duplication type (c). Multisteps (b) or (c) and combinations of steps (b) and (c) can, moreover, lead to various mosaic types. Insertion of host RNA is also observed, especially in plant DI RNA. The frequency at which the polymerase leaps and resumes its synthesis is unknown. The probability for this exercise to be successful in producing a viable DI genome has been estimated for VSV to range in the order of 10^{-7} – 10^{-8} per genome replication.

Defectiveness

The DI genomes contain interrupted or rearranged open reading frames. They partly or completely lack the full coding capacity of the viral genome. They are therefore defective, and depend for their replication and for their propagation (formation of virus particles) on the functions provided by the homologous standard virus (helper). Co-infection of cells with DI and standard particles is therefore essential for DI particle multiplication. Consequently, low-multiplicity infections, and particularly plaque purification, represent conditions which decrease, and potentially eliminate, DI particles from a viral preparation.

Interference

As stated earlier, the generation of a defective genome is likely to represent a rare event. This event would never be seen unless it was successfully amplified. During this amplification step the defective genome is preferentially replicated over the nondefective genome. This ability to replicate efficiently at the expense of the nondefective genome is called interference. The mechanisms of

Fig. 1 Defective RNA genome generation.

interference are not completely understood. They obviously change depending on the specificity of the viruses, and appear to be also affected by the host cell types. In general, interference involves an early step in genome replication, and can be pictured as a competition for limiting replication 'factors' (viral replicase, encapsidation proteins, host cell factors). Reiterated origins of replication or encapsidation sites on DI DNAs, presence of higher affinity sites for the replicase or for the encapsidation on both positive and negative polarity DI RNAs, and shorter length of the replicating units, higher availability for replication of molecules not involved in transcription, have been shown or postulated as taking part in the interference mechanism.

Defective Interfering versus Defective Viruses

Based on the outcome of experimental co-infections of defective with nondefective viruses, a distinction has been made between defective interfering or defective noninterfering particles, according to the ability of the defective viruses to selectively restrict nondefective virus replication. This distinction may not apply during the first events following the generation of a defective genome. As this is bound to be a rare event, an interference mechanism has to be invoked any time this defective genome is amplified to the point it can be detected, or become predominant.

Cyclic Variations of Defective Interference

The dependence of DI genome replication on functions provided by the nondefective genome on the one hand, and the interference exhibited by DI genome on the other hand, result in out-of-phase cyclic variations of both DI and St genome replication. As illustrated in **Fig. 2**, efficient St genome replication must precede extensive DI genome replication. This in turn establishes conditions of high interference which results in inhibition of St genome replication. Decrease of helper function availability leads to DI genome replication dampening, and therefore to release from interference, allowing efficient St genome replication to resume. These cyclic variations have been observed in serial passages of St and DI viruses in cell culture, as well as in persistent infections. The periodicity of a complete cycle is generally a matter of days or of a few serial passages.

Assay for DI Particles

DI particles can be detected by physical separation on velocity or density gradients when applicable (see the section titled 'Structure'). The presence of subgenomic nucleic acids in viral stocks or in infected cells (distinct from viral messengers) can also be diagnostic. The ability to decrease the infectivity of a viral stock or to protect infected cells from the lytic infectious virus (see the section titled, 'Biological effects') are used in various biological assays to estimate quantitatively and qualitatively the DI particle composition of a viral stock. These assays, although appropriate to characterize DI particle preparations, are generally not sensitive enough to exclude, when negative, the presence of DI particles in a viral preparation. The test that still remains the most dependable to assess presence or

Fig. 2 Cyclic variation of DI replication in (a) days, and (b) months.

absence of DI particles consists of multiple independent serial undiluted passages. It is based on the observation that a viral stock contaminated with an undetectable amount of DI particles will, on subsequent independent serial passages, promote in each series amplification of the same contaminating DI particles. A DI particle-free stock, on the other hand, will yield in each series different DI particles or different sets of DI particles.

Biological Effects

DI particles have been shown to modulate the course of an infection. In cell culture, attenuation of the cytopathic effects is the most frequently described, and DI particles can promote cell survival and establishment of persistent infections. As far as negative-stranded RNA viruses are concerned, copy-back DI RNAs appear to prevent induction of apoptosis through a mechanism which has still to be unravelled, in which a certain category of small leader RNAs may participate. A possible role of the matrix M protein, the concentration of which is decreased to the point where viral assembly and budding at the cell surface is highly diminished in the presence of DI genomes, has also been considered. DI ability selectively allows emergence of St virus (St₂) which escapes interference ([Fig. 2\(b\)](#)). St₂, resistant to interference, is selectively amplified over St₁, still sensitive to interference, and soon becomes predominant. It loses its ability to support DI₁, which therefore disappears. St₂ will generate its own DI₂, which in turn will favor emergence of a new St variant. Thus, DI viruses serve as mutational drivers favoring virus evolution, through cycles of high and low interference whose periodicity is this time measured in months or in hundreds of viral passages (compare [Fig. 2\(a\)](#) and [\(b\)](#)).

DI Particles in Experimental Animals

DI particles are generated and amplified in the whole animal, as well as in cell culture. They can change the symptoms of viral infection from rapid death to slow, progressing paralysis. They can sometimes fully protect the animals from an otherwise lethal infection. Interference is likely to be involved in this modulation of symptoms, but other phenomena like increased interferon induction and immune response modulation are reported.

DI Particles in Natural Infections

Involvement of DI particles in natural infections is still poorly documented. This is partly because the experimental results supporting the strong potential for infection modulation of DI particles have not been fully recognized, as detection of DI particles in natural infections is not straightforward. Unpredictable cyclic variations in DI replication, efficiency of DI replication changing with the types of infected tissues, and potent interfering ability associated with poor DI particle replication are all factors which undoubtedly make DI particle detection difficult *in vivo*. Last but not least, virus isolation, which is used to characterize the infectious agent associated with a disease, often represents conditions (low multiplicity of infection) known to impair DI particle replication drastically.

Nevertheless, association of a chicken influenza virus strain, efficiently producing DI particles, with an epidemic of low morbidity and low mortality, and conversely, a high-mortality epidemic associated with a strain free of DI particles, have been reported. Murine and feline leukemia virus strains causing immune deficiency syndromes are shown to contain predominantly replication-defective viral genomes before onset and during the development of the disease. The pathogenicity of some bovine and swine pestiviruses has clearly been associated with presence of DI RNAs in the animals. For the bovine viral diarrhea virus (BVDV), a pestivirus of the same family as hepatitis C virus, the presence of a particular DI RNA can turn noncytopathic virus into a fatal infectious agent. In plants, at least three examples of DI RNAs are described to be involved in infection modulation. Interestingly, depending on the types of viruses, DI RNAs can either attenuate or exacerbate the symptoms.

DI RNAs are identified in stool and blood samples of humans suffering from hepatitis A virus, an infection known to be rather moderate and prolonged. DI particles are identified in measles virus-attenuated vaccine preparations which have been, and are being, widely and successfully used (raising the question of DI particle participation in vaccine attenuation). Measles viruses defective in viral assembly are currently found associated with human subacute sclerosing panencephalitis (SSPE). The brain cells of SSPE patients were, moreover, shown to harbor many species of measles virus copy-back DI RNAs. Direct amplification of a portion of the HIV *tat* gene from infected patients demonstrates that about a third of the sequences correspond to defective *tat* function. Moreover, human immunodeficiency virus (HIV)-1 sequences isolated from a cohort of six blood or blood product recipients infected with one donor all contained a similar deletion in the *nef* gene. Remarkably, all the patients harboring this deleted viral genome remained free of HIV-related diseases 12–16 years after infection, suggesting that this defective species of HIV genome is responsible for this decreased pathology. Epstein–Barr virus (EBV) replicative infections developing in human epithelial lesions involve a deleted rearranged form of EBV DNA (het DNA). This het DNA is associated, in experimental infections, with disruption of latency and persistent productive infections. Specific identification of viral hepatitis B (HBV) genomes containing an interrupted precore antigen (HBcAg) coding sequence in patients dying from fulminant hepatitis suggests that such defective genomes may be responsible for the exacerbation of the disease. This contrasts with more recent data reporting experimental evidence for the existence of DI-like viruses in HBV human chronic carriers; fluctuations between these naturally occurring core internal deletion variants and helper HBV in three chronic carriers were reminiscent of the cycling phenomenon in other DI viral systems.

Future Perspectives

Defective interfering particles are ubiquitous in the realm of animal and plant viruses. In experimental conditions they appear as necessary companions of their nondefective homologs. Capable of affecting the extent of viral growth, the course of viral infections, and serving as selective pressure to drive mutational changes, they can be seen as natural regulators of virus evolution. The demonstration of their participation in natural infections, and of their ability to affect the course of diseases, constitutes a challenge for the years to come. As pointed out by the few examples listed earlier, their direct detection in infected tissues will certainly be needed to assert their involvement in natural infections. The availability of sensitive detection techniques (like polymerase chain reactions), allowing direct observation of viral genomes without the possible distortion of virus isolation, bears great hope. More than giving increased insights into the physiopathology of viral infections, in times where the modifications of the viral genomes represent an imperative step in the generation of viral recombinant vaccines or of appropriate vectors for gene targeting, DI viral genomes represent natural versions of defective genomes that can serve as model tools for creation of more adapted vectors.

Glossary

Auxiliary metabolic genes (AMGs) Genes encoded within viral genomes that potentially function in host metabolic processes.

Lysis Bursting of host cells upon the release of progeny virions after viral infection and replication.

Lysogeny Maintenance of the viral genome within the host, typically either as an inserted “prophage” within the host genome or as an extrachromosomal element similar to a plasmid.

Metagenomics Sequencing and analysis of community DNA, including all genes and all biota from which DNA is extracted from a given sample.

Mycoviruses Viruses that infect fungi.

Temperate Viruses capable of lysogeny or lysis.

Virocell A cell infected by an actively replicating virus; the physiology of a virocell is distinct from an uninfected cell, as metabolism shifts to support viral replication.

Viromics Metagenomics (community DNA sequencing) of the purified viral size-fraction.

Introduction

As members of Earth’s microbiome, viruses exist in consortia that include diverse organisms and other viruses. Even disease-causing viruses of humans, animals, and plants are surrounded by other biota. The focus of this article is on introducing the reader to viruses as members of microbial ecosystems, including the terminology and methods used to study diverse viral communities, the hosts that these viruses can infect, the replication strategies of viruses that infect microorganisms, and the impacts of viruses on microorganisms and the environment. Together, these topics comprise the field of viral ecology, which is the study of viruses as members of ecosystems, including viral diversity and viral interactions with other organisms and the environment.

Depending on the environment, a suite of hosts may exist for the viruses that are present. For example, in soil, hosts could include bacteria, archaea, fungi, protists, plants, insects, and more. In the open ocean, most hosts are likely to be bacteria and other microorganisms, but host-associated viruses are also present in fish, whales, and other creatures. In the human body, there may sometimes be viruses that infect us, like the influenza virus (*Orthomyxoviridae*) or rhinoviruses (*Picornaviridae*) that cause the common cold, but there are also numerous viruses that infect the bacteria in and on our bodies, particularly in our guts. In each of these environments, many viruses co-exist with each other and with a suite of diverse organisms, some of which may be potential hosts. Understanding the different roles that viruses play in these complex ecosystems is one of the main goals of the field of viral ecology.

In addition to the diversity of potential hosts in a given environment, viruses themselves are incredibly genetically and biochemically diverse, which poses a challenge to studying all of the viruses present in a given ecosystem at the same time. Viruses can have DNA or RNA genomes that can be single-stranded or double-stranded, and their genomes can span a wide range of sizes, from just over 1000 nucleotides for some of the smallest circoviruses to 2.5 million base-pairs for some members of the Megavirales group of giant viruses (nucleocytoplasmic large DNA viruses, NCLDV) that infect amoebae. Some viral genomes are spread across multiple segments, while others are contained on a single segment of DNA or RNA. Viruses can be encapsidated within a single protein coat (capsid), or they can be multipartite, with different parts of the genome in multiple capsids. Some viruses are also surrounded by a lipid envelope. Though most viruses can exist as virions in a free particle state in the open environment, some viruses, for example, most mycoviruses (viruses of fungi), are thought to be obligately intracellular and only transmitted vertically from parent organisms to progeny and/or through cell-cell fusion. With all of these different types of viruses, hosts, genome types, replication strategies, and physicochemical forms, it is currently impossible to study all of the viruses in a given ecosystem with a single method. Still, methods for studying viral ecology have vastly improved over the last two decades, and we are getting closer to achieving relatively complete characterizations of viral diversity across environments.

As a field, viral ecology shares some terminology and statistical methodologies with other branches of ecology, particularly with microbial ecology, but there are some important differences. For example, viral population ecology is the study of the diversity, interactions, and processes within a viral population (e.g., growth rates, burst sizes – the number of progeny viruses per infected cell – and controls on these processes), and the study of viral populations is inherently tied to considerations of host populations, as hosts are required for replication. For cellular organisms, populations are typically defined by species boundaries, but there is no simple, universal definition of a viral “species”, nor are there conserved genetic markers common to all viruses, so identifying a meaningful unit of measure to represent a viral population is difficult. And yet, we need to be able to categorize and count viruses within defined groups (populations) in order to take advantage of statistical ecological approaches to compare viral communities. Therefore, a workable definition of a viral operational taxonomic unit (vOTU), or population, is emerging, at least for bacteriophages: genomes and recoverable genome fragments belonging to the same vOTU share an average nucleotide identity (ANI) $\geq 95\%$ along their lengths.

Fig. 1 Epifluorescence micrograph (EFM) of purified viral particles from agricultural soils. 1 ml of post-0.2 μm filtered soil slurry in potassium citrate buffer was placed onto a Whatman 0.02 μm Anodisc filter via vacuum filtration and stained with SYBR Gold. Bright dots are virus-like particles. Image courtesy of Rose Bolle, color-adjusted by JBE for print clarity.

Viral community ecology is a term typically used to mean the study of all viruses recoverable by a given method in a given ecosystem, which is counter to the standard ecological definition of a community, which would include all organisms in a given environment or ecosystem. For simplicity, the viral fraction of an ecosystem is often called a viral community or the virosphere, and, in accordance with field jargon, a viral community in this article includes all of the vOTUs recovered in a given ecosystem by a given method. Similarly, viral community ecology refers to the study of these viruses and their interactions with other organisms and/or the environment. This article will predominantly focus on the emerging field of viral community ecology, which builds on previous studies of single-virus and viral population ecology.

Methods for Studying Viral Community Ecology

Viral communities can be studied with varying levels of detail, depending on the methods used. For many years, continuing today, various microscopic techniques have been used to count the numbers and/or morphological types of viruses in a given community. Transmission electron microscopy (TEM) can resolve viral shapes and can therefore be a useful measure of the numbers of different morphological types of viruses in a given environment. Epifluorescence microscopy (EFM) generally requires adding a fluorescent nucleic acid stain that binds to viral genomes so that the viruses light up under the microscope (Fig. 1). EFM can be useful for counting viruses (or, more accurately, virus-like particles), which appear as bright pinprick dots under the microscope, due to excitation of the nucleic acid stain that emits light. Both of these microscopic approaches can be used to estimate the number of viruses in a sample, which can be extrapolated to estimate the number of viruses in a community or ecosystem. Based on these approaches, the total number of viruses on Earth has been estimated to be approximately 10^{31} , or more than one billion times the number of stars in the Milky Way Galaxy. There are approximately 10^7 viral particles per milliliter of ocean water, and there are approximately 10^7 – 10^{10} viral particles per gram of soil. These counts are based on EFM, which is generally not an effective method for counting viruses with RNA genomes because RNA viruses tend to have smaller genomes that do not stain well, so these approximations, largely based on DNA viruses, may underestimate true, comprehensive viral abundances.

Although microscopy is useful for learning how many viruses are in a sample and for comparing total numbers of viruses among samples, genetic and genomic differences among viruses cannot be determined through microscopy. Some resolution into genomic differences among viral populations has historically been attempted through pulsed-field gel electrophoresis (PFGE), which can distinguish among groups of viruses based on differences in their genome sizes. In this way, a researcher can tell whether a community of viruses from one sample is different from a community of viruses from another sample, based on a “fingerprint” of the genome sizes in each sample. However, many genetically distinct viruses have similar genome sizes and will therefore appear to be the same on a PFGE gel image. So, although PFGE provides slightly more resolution into viral community composition than microscopy, it is still not possible to distinguish among the hundreds or thousands of different viral populations in a given sample through PFGE.

As a further step towards increasing resolution of genetically distinct viral populations, amplicon-based community sequencing can be used to identify specific groups of viruses that share a conserved gene (for example, the gene encoding the g23 major capsid protein of T4-like bacteriophages). This allows for very high resolution into the specific viral populations that contain a specific gene of interest in a given environment. Similar to approaches for characterizing bacterial and archaeal community composition through 16S rRNA gene amplicon sequencing, these specific viral genes can be amplified directly from DNA extracted from the

environment through polymerase chain reaction (PCR). The amplified PCR products contain DNA sequences from each viral population that has this gene in a given sample, thus these PCR products can be sequenced to determine viral population diversity and the relative abundances of each viral population in each sample. Comparing all viral populations that have the gene of interest across samples is also possible via this approach, so this amplicon sequencing technique can provide some insights into viral community ecology, but only for a specific viral group with the gene of interest. For these specific viruses, this may be an excellent approach. However, there is no universal marker gene for viruses, so it is impossible to capture all of the viruses in a given ecosystem through amplicon-based sequencing.

Shotgun metagenomics, or sequencing all of the DNA in a sample, is an approach that comes close to identifying most of the viruses with DNA genomes in a given community. Typically, viral particles are purified from the environment based on their relatively small size through filtration (e.g., by passing a liquid sample through a 0.2 μm filter that removes most bacteria and larger organisms). Filtration is relatively straightforward for aqueous samples, but it generally requires the addition of a buffer and some pre-processing to remove solids from soil or sediment samples. Once the viral particles have been purified from other organisms, the viral community DNA can be extracted and sequenced, and the recovered viral genomes can be reconstructed on the computer via bioinformatics. This approach – purifying viral particles and sequencing and analyzing the viral metagenome – is called viromics. To date, viromic approaches have been used to recover hundreds of thousands of ocean viral populations and thousands of soil viral populations, and the number of viral populations that we are able to recover via viromics continues to increase, such that the actual viral diversity of these ecosystems remains to be seen.

Even with viromics, we cannot study all viruses in a given ecosystem because not all viruses have DNA genomes, and viromics only recovers viruses with DNA genomes. In addition, by purifying viral particles prior to metagenomics, we are only considering viruses that have (and, at the time of sampling, are in) a free viral particle phase, so we will miss viruses that are: integrated in host genomes (see lysogeny in the glossary and later in this article), undergoing active infection and replication inside a host cell, or never have a free viral particle phase in the open environment. Attempts to recover these other viral genome types and replication stages are being made via metatranscriptomics (recovering all of the RNA in a sample) and via bioinformatic mining of viral genomic signatures from total metagenomes. For example, instead of purifying viral particles, shotgun metagenomics or metatranscriptomics can be performed directly on an environmental sample, such that most sequences will be recovered from the dominant organisms in the sample (generally bacteria for marine and soil samples). In the remaining sequences, we can predict genes and proteins to look for viral hallmarks, like capsid proteins, to identify viruses that may not have been recovered in purified viral metagenomes (viromes). Together with long-read sequencing approaches that are beginning to recover complete and near-complete viral genomes in a single sequence, our ever-improving laboratory and bioinformatics approaches to viral ecology are allowing us to access more and more populations and replication stages within each viral and microbial community.

Virus-Host Linkages and Ecology

Most of the subsequent sections in this article will focus on viruses of bacteria (bacteriophages) because our existing viromic methods are best suited to recovering bacteriophages with double-stranded DNA genomes, so we have the most information about bacteriophage ecology. However, as methods continue to improve, we are beginning to uncover diverse viruses in nature that infect other organisms, including eukaryotes. The vast majority of plant and fungal viruses have RNA genomes, so our metagenomic and viromic approaches will not recover these viruses, but metatranscriptomic (shotgun RNA sequencing) approaches have shown that diverse RNA viruses are present in the environment. For example, diverse RNA viruses have been recovered from marine systems and soil, including many putative soil mycoviruses that have vastly expanded the known genomic diversity of mycoviruses. It remains to be seen whether these putative mycoviruses do in fact infect fungi; linking viruses to eukaryotic hosts is currently difficult and is based on shared sequence homology between viruses recovered in a metatranscriptome and known viruses (i.e., viruses with known eukaryotic hosts) in public databases. The more similar the unknown viral sequence in a given metatranscriptome is to a virus in a public database, the more likely it is that they share a host.

Although existing methods are imperfectly suited to identifying divergent viruses with RNA genomes and their (mostly) eukaryotic hosts, bioinformatic methods for linking DNA viruses to host bacteria are much better and continue to improve. For example, some bacteria have clustered regularly interspaced short palindromic repeat (CRISPR) regions that provide adaptive immunity to mobile genetic elements, including viruses (Fig. 2). These regions of some host bacterial and most archaeal genomes contain pieces of DNA from the genomes of viruses that previously infected that host population, allowing the host to recognize and mitigate a new infection from another member of the same viral population based on sequence homology. The host uses the DNA from previous viral infections, contained in its own CRISPR region, as a homing device to identify the same viral sequence in an invading virus. This fascinating mechanism has been adapted as the mainstay of cutting-edge genetic engineering approaches, but for purposes of viral ecology, we can take advantage of the host CRISPR region and viral genomes to link viruses to host bacteria on the computer. Simply comparing the sequences from the host's CRISPR region to viral sequences and looking for exact matches provides a strong indication that a matching viral population has infected that host population in the recent past. With these virus-host linkages, we are beginning to be able to unravel virus-host population dynamics in nature. For example, ratios of virus-host abundance in thawing permafrost soils were shown to vary by host lineage, potentially indicating host lineage-specific differences in viral infection dynamics in response to changing environmental conditions.

Fig. 2 CRISPR regions of microbial genomes, used to link viruses to bacterial and archaeal hosts through shared sequence homology.

Fig. 3 Schematic overview of common replication strategies for viruses of microorganisms. Orange represents the viral genome, and purple represents the host genome.

Viral Impacts on Carbon, Nutrient, and Biogeochemical Cycling

Viruses of bacteria and archaea typically undergo one of two replication cycles: the lytic or the lysogenic cycle (**Fig. 3**). In the lytic cycle, viral infection leads to near-immediate viral replication inside the host cell and results in cell lysis (bursting) upon the release of progeny virions. In the lysogenic cycle, viral DNA is typically inserted into the host chromosome or maintained extrachromosomally and can therefore be replicated passively through host cellular division unless and until the virus is signaled to undergo the lytic cycle. Temperate phages can undergo the lysogenic or lytic cycles, depending on host and environmental cues, while lytic or virulent phages exclusively undergo the lytic cycle. There are many known chemical and environmental inducing agents that can drive a shift from the lysogenic to the lytic cycle, and these inducing agents generally signal that the current host may soon no longer be viable or that new hosts are likely to be available nearby. For example, known inducing agents include mitomycin C (an antibiotic), ultraviolet (UV) light, and bacterial quorum-sensing molecules, such as *N*-acyl-homoserine lactones (AHLs), all of which have been used in laboratory experiments to induce lysogens to undergo the lytic cycle for recovery in the free viral fraction. Additions of inducing agents to bacterial communities have allowed for bulk estimates of lysogenic viral abundances in soil, sediments, and seawater and have demonstrated seasonal shifts in temperate phage communities from predominantly lysogenic to predominantly lytic in polar marine environments.

These viral replication strategies can have important implications for microbial ecology and biogeochemistry. For example, lysis can contribute to carbon and nutrient cycling by releasing host cellular contents into the environment when the host cell bursts, and an estimated ~20%–40% of marine microbial cells undergo viral lysis daily in the global oceans. In marine and freshwater

systems, lytic events and viral infection in general can mitigate harmful cyanobacterial and algal blooms, alleviating the ecological impacts of eutrophication (excessive nutrient richness, resulting in removal of oxygen) and fish toxin production caused by these microorganisms. In terms of microbial community structure and function, lysis results in host mortality, impacting metabolic functions performed by infected host populations, while lysogeny may increase the fitness of specific host populations by contributing new genes and, therefore, new functional potential. Generally, lysis is presumed to be the dominant viral replication mode in most marine systems, though only a relatively limited number of community-scale evaluations of lysis and lysogeny have been attempted on seawater communities to date. Conversely, it has been hypothesized that temperate phages dominate in soil environments, which could mean that soil viral ecology is fundamentally different from lysis-dominated marine ecology, but this hypothesis has yet to be thoroughly tested.

Given that viruses rely on host cell machinery for replication, it is well known that viruses hijack the host cell throughout the infection cycle, altering host gene expression and metabolism. An infected host cell that contains an actively replicating virus is known as a “virocell”, and the physiology of a virocell is substantially shifted towards metabolic pathways required for viral replication, such as nucleotide biosynthesis. Interestingly, despite by definition not possessing their own metabolism or means of energy conservation, some viruses can also express their own genes to contribute to host metabolism during an active infection. For example, virus-encoded photosynthesis genes can be expressed during cyanophage infection of Cyanobacteria to plug a host metabolic bottleneck, keeping the Cyanobacteria just healthy enough (photosynthesizing just enough) to complete the viral replication cycle. By expressing such virus-encoded auxiliary metabolic genes (AMGs) during infection, viruses are thought to directly impact carbon, nitrogen, sulfur, phosphorous, and other biogeochemical cycles. Although the strongest evidence in support of direct viral AMG impacts on biogeochemistry at ecologically meaningful magnitudes is from cyanophage photosynthesis genes (in some cases, over 50% of the *pbsA* transcripts recovered in marine metatranscriptomes were of viral, as opposed to cyanobacterial, origin), many other host-like metabolic genes have been found in viral genomes, highlighting the intriguing possibility that viruses may impact a suite of biogeochemical cycles by expressing their own versions of metabolic genes during infection. For example, reverse dissimilatory sulfite reductase (*rdsr*) and *sox* genes with presumed roles in sulfur oxidation have been recovered in marine phage genomes, as have genes encoding a wide range of proteins involved in central carbon metabolism, along with the *P-II* gene that encodes a protein regulator of multiple nitrogen-cycling metabolic processes. AMGs that encode ammonia oxidation proteins (e.g., ammonia monooxygenase, *amoC*) have been recovered from marine archaeal viruses, and genes that encode proteins for complex carbon degradation to simple sugars have been recovered from soil viral genomes.

Drivers of Viral Community Composition

Now that methods are available for identifying and counting diverse viral populations (vOTUs) based on sequences recovered from viromes and total metagenomes, the field of viral ecology has begun to leverage established statistical ecological approaches to compare viral community ecology among samples and across biogeochemical conditions. The most substantial advances in this area have come from marine systems, from which hundreds of thousands of viral populations have been recovered and their relative abundances counted and compared. Considering pairwise comparisons of geographically adjacent ocean viromes, with adjacency considered both in terms of surface coordinates and depth within the water column, evidence suggests that viruses travel along ocean currents and tend to sink, perhaps contributing to the sinking aggregates that comprise marine snow and move surface carbon to the deep sea. Locally, marine viral community composition tends to correlate with environmental conditions known to structure host microbial communities, such as oceanic region (Longhurst province), biome, latitude, temperature, and oxygen concentrations, suggesting, perhaps not surprisingly, that viruses tend to be found where their hosts are.

Changes in viral population dynamics and community composition over time have also been explored in aqueous systems. In hypersaline lakes, viral populations were generally found to be highly dynamic over a three-year period, with some populations detected in only a handful of samples, suggesting that viruses are moving in and out of the ecosystem (or at least substantially changing in abundance) over relatively short time scales. In marine systems, seasonal and diel viral dynamics have been observed, suggesting that viruses respond to seasonal changes in temperature, nutrients, and/or host abundances, along with diurnal changes in host dynamics. The predominant bacterial hosts in the surface oceans are photosynthetic and therefore change their expression in response to light, and it appears that, at least to some extent, viral abundances track these patterns of host dynamics. Presumably, most viral responses to changing conditions are indirect responses to those conditions by way of more direct host responses, but there is also some evidence to suggest that viral infection success and population dynamics are directly tied to environmental drivers of viral decay and adsorption dynamics, though to what extent the environment impacts viral infection at an ecologically relevant scale remains to be determined.

Limited information is available for viral community ecology in soil, though the soil viral ecology field is projected to move at a rapid pace, now that laboratory methods for purifying viral particles from the soil matrix have caught up to cutting-edge bioinformatics approaches for reconstructing viral population genomes. Soil viral communities have been shown to contain thousands of diverse viral populations, and these viral communities have been shown to differ by habitat along a permafrost thaw gradient. Differences in viral community composition in thawing permafrost correlated with bacterial and archaeal community composition and known drivers of microbial community composition, including pH and soil moisture content. At this coarse community scale, it would appear that viruses simply follow their hosts, but at the level of individual microbial lineages, evidence suggests that viral abundances are not solely driven by the abundances of their hosts and may be impacted by environmental conditions.

The Role of Retroviruses in Cellular Evolution

Andrea Kirmaier and Welkin E Johnson, Boston College, Chestnut Hill, MA, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Endogenous retrovirus A locus in an organismal genome comprising a complete or partial retroviral provirus; opposite of 'exogenous'.

Exaptation A special form of adaptation involving cooption of an existing trait for a new function.

Exogenous retrovirus A retrovirus that spreads by horizontal transmission from one host organism to another.

Host dependency factor (HDF) Any cellularly encoded protein a retrovirus depends on for the completion of its replication cycle.

Indel Combined abbreviation for 'insertion/deletion'; mutations resulting from the insertion or deletion of segments of DNA.

Provirus Integrated DNA copy of a retrovirus' RNA genome.

Restriction factor (RF) A cellularly encoded protein with direct anti-viral activity.

Introduction

Retroviruses may have originated more than 400 million years ago, close to the dawn of vertebrate life on earth. It is therefore reasonable to expect that the evolution of vertebrate organisms, as hosts, has been continuously shaped and reshaped by retroviral agents over such vast expanses of evolutionary time. Like all viruses, retroviruses are obligate intracellular parasites and depend on host cells for replication and the generation of progeny virions. What distinguishes retroviruses from most other vertebrate viruses, and adds to their role as selective agents, is their particular mode of replication: all retroviruses replicate by reverse-transcribing the viral RNA genome and integrating the resulting DNA copy permanently into the chromosomal DNA of an infected cell. The resulting insertion is called a provirus, which comprises the minimum set of viral regulatory elements and viral protein-coding genes necessary for expression and propagation of the next generation of progeny virions. The provirus remains as a novel genetic insertion in the host chromosome for as long as the cell itself persists. In the case of dividing cells, the provirus is copied as part of the normal process of chromosomal DNA replication and a copy of the provirus is inherited by each of the daughter cells.

To the extent that any virus causes disease or pathogenesis and affects host fitness, it can act as an agent of natural selection driving changes in alleles of genes that affect susceptibility to infection (or its consequences). Retroviruses are no exception. However, as a consequence of integration, retrovirus infections are often persistent and can result in chronic diseases. Because of integration, retroviruses are also potentially mutagenic, causing disruption or dysregulation of genes and activation of oncogenes (Fig. 1). If integration occurs in germline tissue, producing a heritable provirus known as an endogenous retrovirus (ERV), any phenotypic consequences of insertion are also potentially heritable (passed on to the host's offspring). In such cases, the ERV insertion itself can be subject to selection. Importantly, as with any other alterations to an organism's germline DNA, an ERV may be deleterious, beneficial, or neutral with respect to host fitness.

Molecular Consequences of Retrovirus Integration

The genetic effect of proviral integration into the host genome can be determined in part by the site of integration. Different kinds of retroviruses display preferences for different genomic contexts. Many preferentially integrate into functional regions of the host genome. For example, retroviruses in the genus *Lentivirus*, such as HIV-1, tend to integrate in actively transcribed host genes. Disruption of a host gene's coding region can result in a loss of protein expression from that locus, and a loss of the protein's function in the cell.

Altered gene regulation is another potential consequence of proviral integration. Host gene dysregulation can stem from a loss or disruption of a gene's native regulatory elements (promoter, enhancers, transcription factor binding sites) caused by the integrating provirus, and/or it can stem from the proviral long-terminal repeats (LTRs) acting on nearby genes. LTRs contain the viral promoters and transcription factor binding sites, which can interact with regulatory factors provided by the cell to influence regulation of nearby genes, imposing the virus' regulatory program. Since viral promoters are generally fairly strong, increased and/or aberrant transcription of neighboring host genes can result. Alteration of host gene expression is often seen in infections with viruses in the genus *Gammaretrovirus*, such as Murine Leukemia Virus (MLV), which prefer to integrate near transcriptional control elements such as promoters, transcriptional start sites and enhancers. Moreover, if provirus-mediated dys-regulation happens to genes involved in cell cycling, cells can start to proliferate uncontrollably and ultimately give rise to cancers.

A third way in which retroviral proviruses can genetically interact with the host is through the accidental generation of novel protein products originating from alternative mRNA splicing. Proviruses contain multiple splice donor and splice acceptor sites for

Fig. 1 Genetic interactions of a retroviral provirus with the host genome. The center of the figure depicts an integrated provirus (gray and colored rectangles) flanked by host chromosomal DNA (wavy lines). The provirus comprises LTRs, which contain most of the cis-acting regulatory elements of the virus, and the viral genes (in the illustration, only the canonical *gag*, *pol* and *env* genes are shown). The provirus directs expression of viral genes and the production of progeny virions (not shown). Proviruses can exist in multiple forms; in addition to fully intact proviruses with all regulatory and coding sequences, proviruses can be partially or completely defective for expression due to mutations and indels (exemplified in sub-figure 3, bottom). The provirus can have a variety of effects on host genes: (1) The presence of a provirus or a solo-LTR can disrupt the coding sequence of host gene X, which may result in a non-functional host protein X. (2) A provirus or a solo-LTR near the 5' end of a host gene can cause aberrant transcription of the host gene due to disruption of the host gene regulatory regions or due to the proviral LTR serving as the new regulatory element. Changes in both quantity (i.e., how much) or quality (i.e., when/where) of transcription of gene X are therefore possible. (3) Provirus sequences can give rise to novel splice variants of host genes, for example, if the host gene X transcripts are fused with viral transcripts by altered RNA splicing. This can occur both at the 5' and the 3' end of host gene X (only 3' end is shown; dotted lines = splice junctions). (4) Proviral sequences can be co-opted by the host (a unique form of adaptation known as exaptation). For example, if the expression of a viral protein or altered regulation of a host gene confers a selective advantage to the organism, there is a chance of the novel genetic variant being favored by natural selection. While scenarios (1), (2) and (3) can happen as a consequence of both somatic and germline integration, scenario (4) is exclusive to insertions into the germline (i.e., ERVs).

the generation of sub-genomic mRNA transcripts. Should a provirus integrate within the coding region of a host gene, such that a read-through mRNA is generated by DNA Pol II, the viral splice donors and acceptors can pair with host splicing elements, and thus produce chimeric transcripts. This mechanism can give rise to alternative isoforms of the host mRNA, and even produce novel proteins that are part host-derived, part virus-derived.

Finally, segments of integrated proviruses found in the genomes of many vertebrate organisms, known as endogenous retroviruses (ERVs), can be co-opted by evolution to provide useful cellular functions. This evolutionarily important phenomenon, sometimes referred to as *exaptation*, is discussed further in a later section.

Retroviruses Can Drive Evolution of Host Genes

Retroviruses cause persistent infections, and collectively have been associated with a spectrum of chronic diseases, including various malignancies and immunodeficiencies. To the extent that chronic, long-term infection and its pathogenic consequences reduce the reproductive fitness of host organisms, retroviruses can act on a host population as agents of natural selection, altering allele frequencies of genes that reduce or increase susceptibility to infection and/or severity of disease. Hypothetically, this can encompass a variety of types of genes, including: (1) genes that encode "host dependency factors (HDFs)", which are factors hijacked by viruses for optimal replication and spread; (2) restriction factors (RFs), which are cellular factors that have evolved to

Fig. 2 Retroviruses as selective agents. Any type of host traits or factors that positively or negatively contribute to a retrovirus' ability to infect, replicate and disseminate within and between hosts, may be subject to selection by the virus. There are two general types of host traits and factors relating to retroviruses: (i) traits/factors required for or helpful to the generation and/or spread of progeny virions (designated by "+", left side), and traits/factors impeding the generation and/or spread of progeny virions (designated by "-", right side). Due to retroviral pathogenicity, variants of restriction factors and other innate and adaptive immune effectors with better anti-viral function will be positively selected, as they will result in higher resistance to retroviral infection (purple and orange circles). On the other hand, a retrovirus will convey a selective advantage to individuals encoding alleles of host dependency factors (HDF) that are less suited to interact with the virus, and it will conversely negatively select alleles of HDFs that better support interactions with the virus (blue circle). Other, more complex traits, such as behavior or habitus can also affect the efficiency of retroviral replication and spread, and will be selected accordingly (green circle). For example, higher aggression might lead to more fighting, which can increase the chance of exposure to a virus through direct contact with blood. In this case, the virus would indirectly select for more docile individuals, as they would have a lower chance of contracting an infection through contact. Prolonged, i.e., multi-generational exposure of a population to a retrovirus will result in changes of host allele frequencies based on selection by the virus.

block or suppress viral replication at the level of the cell; (3) adaptive and innate immune factors, including pattern-recognition receptors, effectors, and signaling molecules; and (4) other, more complex traits (Fig. 2).

Host dependency factors (HDFs)

As with all viruses, retroviruses hijack the molecular machinery of the host cell for the purpose of replication and production of progeny genomes and virions. This can involve numerous molecular interactions between viral macromolecules and host factors involved in nucleic acid synthesis, transcription, translation, post-translational modification, nuclear import/export, sorting and trafficking, etc. There is some evidence that retroviruses may select for changes in host dependency factors, the simplest hypothesis being selection should favor changes that eliminate the interaction (and thereby reduce the host's susceptibility to infection or disease). Here, selection may involve a trade-off between reduced cellular function and increased resistance. The classic, non-retroviral example of such a trade-off involves the parasite that causes malaria and the sickle-cell trait that is common in areas with endemic malaria. Despite the deleterious effects of the sickle-cell trait, the increased resistance to malaria favors heterozygous individuals (with one copy of the mutant allele) and thereby maintains the sickle cell mutation at higher than expected frequency. Currently, the best evidence for such trade-offs involving retroviruses comes from adaptations in various cell-surface proteins exploited by retroviruses as entry-receptors. However, it is reasonable to expect that selection has involved trade-offs to reduce or alter other kinds of virus-host molecular interactions.

Restriction factors (RFs)

Currently, the best evidence for selection driven specifically by retroviruses comes from comparative analysis of several well-known restriction factors, including APOBEC3G, TRIM5alpha, BST2/tetherin, SAMHD1 and Mx2. Interspecies comparisons of such genes often reveal signatures of positive selection (selection for changes in amino-acid sequence) affecting subdomains known to interact directly with viral targets or proteins. In some cases, cell-culture experiments and animal models have corroborated the hypothesis that retroviruses may have been the agents of positive selection, primarily by showing that the putatively selected amino-acid changes disrupt or diminish interactions with known retroviral targets. While this kind of evidence is indirect, such patterns suggest that the changes were selected by virtue of conferring resistance to one or more retroviruses in the past.

For example, the cytoplasmic TRIM5alpha protein recognizes and coats the hexameric lattice of retroviral capsid shells in the cytoplasm, thereby blocking subsequent stages of the replication cycle. A comparison of TRIM5alpha orthologs from humans and

other primate species reveals a large number of variable residues in the subdomain involved in capsid recognition, and indeed, the differential ability of primate TRIM5alpha homologs to restrict various retroviruses maps precisely to these same variable sites. This supports the hypothesis that divergent evolution of TRIM5alpha sequence between primates may have been driven by selection in the form of retroviral pathogens. Similar patterns have been reported for several other restriction factors, including APOBEC3G, BST2/tetherin and SAMHD1, among others. In fact, evidence for positive selection has become a commonly applied criterion for discovering putative restriction factors.

Host immunity

Selection on adaptive immune factors, such as antibody genes and MHC, is also likely but more difficult to establish, as these loci likely adapt to a broad array of pathogens (including but not limited to many different kinds of viruses, bacteria and eukaryotic parasites). Studies of HIV-1-positive patient cohorts have clearly identified different MHC alleles associated with positive and negative outcomes – thus, it is possible that an epidemic (such as the HIV-1/AIDS pandemic), extended across multiple generations of a population, could result in selection for increased frequency of protective alleles and reduced frequency of alleles that enhance infection or disease.

Host genes with indirect effects on retrovirus infection, spread or disease

In addition, it is possible that adaptations in any gene or gene network could reflect selection by retroviruses – for example, changes that manifest as alterations in behavior could be so selected, if the result is reduced susceptibility to infection or disease. Presently, there is very little documentation to support this speculative hypothesis, and the idea remains to be investigated.

Germline Insertions (Endogenous Retroviruses) Can Generate Genetic Novelty

Endogenous retroviruses (ERV) are germline-integrated proviruses, and, in contrast to exogenous retroviruses, are part of the heritable genetic information of the host. An organism that originates from a germline cell containing a provirus will have a copy of this provirus in every nucleated cell. Over time, the ERV locus can even become fixed in a population, such that most or all members of a diploid population carry two copies of the ERV locus (one on each chromosome) (**Fig. 3**). The genomes of many vertebrate species contain thousands of ERV loci, ranging in age from thousands to tens of millions of years old. For example, approximately 8% of the human genome, equivalent to hundreds of thousands of loci, are of retroviral origin (for comparison, less than 2% of the human genome comprises protein-coding genes).

As with other genomic loci, ERV insertions will accumulate mutations over generational time and will diverge from the original proviral sequence. ERVs can therefore exist in several states: intact ERVs (retaining both LTRs and most or all coding regions) are usually less than 1 million years old, while more degraded ERVs tend to be older. Point mutations or short indels can inactivate open reading frames and regulatory sequences, so the viral genes are no longer transcribed. Very old ERVs (tens of millions of years and up) typically have accumulated larger deletions and insertions as well as point mutations. Homologous recombination frequently occurs between the 5' and 3' LTRs, which removes the intervening portion of the provirus and leaves behind a solo-LTR. Notably, solo-LTRs often outnumber other forms of ERV by an order of magnitude or more, and are the most common form of ERV element found in vertebrate genomes.

At the time of germline integration, an ERV effectively becomes just another genetic element of the host genome, and as with the rest of the genome, it will be subject to random genetic drift and selection based on whether or not it contributes to host fitness. In fact, there are many documented examples of ERV regulatory elements and ERV protein-coding reading frames retaining (or acquiring) functions beneficial to the host organism. This process is commonly referred to as “co-option” or “exaptation”.

Exaptation of ERVs

There are two general ways by which an ERV might be co-opted by host evolution: (i) exaptation of viral protein-coding genes, when one or more of the retroviral proteins provides a new cellular function, and (ii) exaptation of viral regulatory elements, such as those found in the LTRs, to alter the regulation or expression of cellular gene(s) in a manner that is selectively advantageous to the organism.

Exaptation of ERV-encoded envelope glycoproteins

The best-documented examples of co-option of retroviral proteins involve retrovirus entry glycoproteins (Env). The Env proteins are initially expressed on the surface of the infected cell, and incorporated into progeny virions as they bud from the cell. The primary viral functions of Env proteins are (1) binding to a cognate cell-surface protein that functions as the viral entry receptor, and (2) providing the mechanical energy to fuse the virion and cellular membranes and permit the viral genetic material to enter the cell. In some cases, expression of the Env protein also has a third function (3) blocking receptor availability on the infected cell, which can block reinfection. This phenomenon is known as superinfection interference. In cases where ERV-derived Env glycoproteins have been coopted, the cellular function usually capitalizes on one or more of these three activities.

Fig. 3 Origin of ERVs. An exogenous retrovirus can infect somatic or germline cells. In somatic infections, the integrated provirus will persist for the lifetime of the infected cell but it will perish when that cell dies, and the provirus is not heritable. In germline infections, the integrated provirus becomes part of the heritable information of the host (green, magenta, yellow, blue). If an organism with a germ-line integrated retrovirus has offspring, each nucleated cell in the offspring's body will contain a copy of the provirus, including germline tissue that produce gametes – thus, the offspring can pass on the ERV locus to its own offspring, and so on. Over time, an ERV locus can be lost from a population (green, magenta, yellow) or it can increase in frequency and eventually become fixed, i.e., every organism of the population carries the locus (blue). Early on, any individuals that carry the insertion have one copy, i.e., they are heterozygous. As the frequency of the insertion increases, individuals are increasingly likely to carry copies on both chromosomes, i.e., they are homozygous. The ERV locus will also usually accumulate mutations, including mutations disrupting the coding and/or regulatory functions (dark gray triangle). As a consequence of endogenization, ERV sequences can persist long after the original exogenous retrovirus has gone extinct.

The mammalian Syncytins are the best documented example of exapted ERV-encoded Env proteins. These proteins are expressed in trophoblast cells during embryonic development, and function to drive fusion of trophoblast cells to form the syncytiotrophoblast layer. This involved evolutionary repurposing of both the viral receptor-binding and membrane fusion functions of Env. Syncytins and syncytin-like ERV elements have been found in all mammalian clades, including marsupials, as well as in some live-bearing reptiles, indicating that retroviruses have been repeatedly involved in the evolution of live birth.

The ability to bind their cognate receptor also selected for the use of ERV Env proteins as antiviral defenses. Because ERV-encoded Env may retain the ability to bind and block the virus's cognate cell-surface receptor (analogous to superinfection interference), the expression of the ERV Env can inhibit infection by exogenous viruses using that same receptor, thereby providing resistance to infection. In such cases, the former viral Env glycoprotein has in essence become a restriction factor. Examples of this process include the mouse *Fv4* gene, which provides resistance to infection to murine leukemia virus (MLV) by downregulating the viral receptor, and the feline *Refrex* genes, which block infection by feline leukemia virus (FeLV) by a similar mechanism. There is evidence that an ERV in the human genome, known as HERV-T, may have had similar activity against a retrovirus that afflicted our ancestors.

Exaptation of ERV-derived non-coding elements

The provirus contains all of the essential regulatory and cis-acting elements required for expression of the viral genes. For example, the LTRs contain the primary viral promoter, transcription factor binding sites, and signals for mRNA termination and polyadenylation. ERVs in organismal genomes may retain some or all of these elements, and there are now multiple reported examples of co-option of ERV LTRs as components of the regulatory pathways of vertebrate genes and gene networks. For example, the

human globin locus is under the control of an ERV9 LTR, while ERV LTRs upstream of the human *AMY1* genes drive tissue-specific expression of amylase in salivary glands. A particularly striking example of ERV LTR exaptation comes from the discovery that gene regulatory networks involved in innate immunity in mice and humans are regulated, at least in part, via ERV LTRs that have been coopted as cis-acting regulatory elements. Such discoveries lead to the hypothesis that ERV may serve an important evolutionary function by facilitating the formation or rewiring of gene regulatory networks.

Exaptation of other ERV-derived proteins

There is a small but growing list of other ERV-derived retroviral genes that exhibit cellular functions. There is at least one example of a host gene resembling a retrovirus-related protease, known as SASPase. Perhaps the best studied example is the rodent *Fv1* gene, which functions as an ERV-derived restriction factor that can block infection by a wide variety of retroviruses. *Fv1* encodes the remnants of a retroviral *gag* gene, and its expression restricts exogenous retroviruses at an early, post entry stage in the viral replication cycle, possibly via a direct interaction with the capsid shell of the incoming virus as it penetrates the cytoplasm. Another example of exaptation of a retroviral *gag* gene is found in sheep, and confers resistance specifically to the oncogenic Jaagsiekte sheep retrovirus (JSRV). Although such examples are limited, the presence of intact ERV-encoded open-reading frames in the genomes of many vertebrates, including humans, raises the possibility that many more examples will be discovered. Finding candidate sequences is relatively straightforward; the difficulty lies in establishing function, particularly in non-model organisms.

Summary

Darwinian evolution is the combined result of variation and natural selection. The sheer abundance of ancient ERV found in vertebrate genomes, and the widespread presence of extant retroviruses found in nature, together indicate the potential for retroviruses to have had a significant impact on the origins and evolution of vertebrate species. This impact is two-fold: retroviruses can exert selective pressure on host populations, and ERV insertions in the germline can contribute to genetic variation within organismal populations. Going forward, comparative genomics and experimental models will continue to uncover additional examples and help document the actual extent to which retroviruses (and the related LTR-retrotransposons) have contributed to the evolution of cellular organisms.

The Role of Bacteriophages in Bacterial Evolution

Chris M Rands, University of Geneva Medical School and Swiss Institute of Bioinformatics, Geneva, Switzerland

Harald Brüssow, Laboratory of Gene Technology, Department of Biosystems, KU Leuven, Leuven, Belgium

Antagonistic Phage-Bacterium Relationships

Seminal publications influence the scientific discussion well beyond the data described within that specific report. This was certainly the case for the first report describing the discovery of bacterial viruses. Already the naming of bacterial viruses as “bacteriophages” (bacterial eaters) by Félix d’Hérelle in 1917 set the stage for bacteriophages as natural enemies of bacteria. Based on this concept of a predator-prey relationship, phages (short for bacteriophages) were used in the Soviet Union as antimicrobial agents (“phage therapy”) well before the development of antibiotics. This concept of phages as killers of bacteria received strong support in a 1989 study in which Norwegian marine microbiologists reported high viral titers in the ocean and freshwater systems exceeding that of bacteria by a factor of ten. When other microbial ecosystems were explored (soil, plant roots, human gut) the viral to bacterial ratio differed according to the particular ecological situation. However, a clear trend emerged: phages represented the major causes of bacterial mortality in the ecosphere, together with starvation and grazing by protists. Under such a strong selection pressure, one could anticipate a fierce evolutionary arms race between bacteria and phages. Indeed, another seminal paper from 1943 by Luria and Delbrück reported overnight resistance development in bacteria exposed to phages, followed by the development of mutant phages overcoming this bacterial resistance, followed by bacteria becoming resistant to these mutant phages. This so-called Red Queen paradox revealed phages are major drivers of bacterial evolution.

The then young field of molecular biology concentrated their efforts on the study of *Escherichia coli* phages, describing their sophisticated hijacking of the bacterial host metabolic and genetic apparatus. However, bacterial countermeasures against phage attack in the form of restriction-modification (R-M) enzymes were also soon described. When genomics emerged from genetics, the important role of phage-bacterial competition in their coevolution could be read from their genomes. Comparative *E. coli* genomics revealed R-M genes and genes synthesizing lipopolysaccharides (a frequently used primary receptor for phages) as two of the most hypervariable genomic regions in *E. coli* demonstrating that they are under strong selective pressure. Comparative phage genomics showed that phage tail fiber tips, which mediate the first contact with the bacterial receptors, are the principal hypervariable phage genome regions. As such, this genome analysis reveals the foot prints of the arms race between phages and their bacterial hosts.

When molecular biology shifted to more complex model systems, applied scientists dealing with the problem of phage control in the dairy industry maintained phage research and discovered numerous anti-phage defense mechanisms, mostly encoded on plasmids of *Lactococcus lactis*, the major cheese starter bacterium. When these abortive infection (*abi*) genes were introduced into industrial starter bacteria, mutant phages overcoming these resistance mechanisms were frequently documented. Surprisingly, the starter bacterium used in yogurt fermentation, *Streptococcus thermophilus*, suffered a lot from phage attack (Fig. 1), but lacked plasmids and *abi* genes. This paradox led to the discovery of genetic loci on the *S. thermophilus* genome that contained short DNA copies of various dairy phages. These “Clustered Regularly Interspaced Short Palindromic Repeats” (CRISPR) together with “CRISPR-associated” (*Cas*) genes, which encode enzymes that use CRISPR sequences as a guide to recognize and cleave matching DNA in phages, turned out to be the major anti-phage system in *S. thermophilus*. Follow-up research revealed that CRISPR-Cas systems are very diverse and widespread in bacteria and nearly omnipresent in archaea, reflecting the strong impact of phages on bacterial evolution.

While this research identified phages as foes of bacteria locked with their hosts in an age-old and ongoing arms race, ecological theory predicts advantages of predation for other potential prey at the population and ecosystem level. In this area, marine microbiologists took the lead. One concept was that phages, when lysing their host, release nutrients that feed bystander bacteria. Phages thus maintain nutrients in the microbial loop and prevent their loss in the food chain and sedimentation to the bottom of the ocean. As such, phages are now revealed as important drivers of geochemical cycles. Another beneficial role of phages was identified by marine microbiologists based on the threshold concept. Laboratory experiments with coliphages had demonstrated that phages do not infect low abundance bacteria and oceanographers developed the “killing the winning” concept, in which phages efficiently infect outgrowing bacteria in “blooms”. This concept represents a powerful mechanism maintaining bacterial diversity in an ecosystem. Support for this concept has also come from medical microbiologists, demonstrating that *Vibrio cholerae* epidemics show rhythmic alterations with the outgrowth of *V. cholerae*, followed by that of vibriophages in the environment.

Marine microbiologists have opened an important chapter in phage-bacterium coevolution by investigating their interaction in natural ecosystems outside of the laboratory. Historically, phage research has been dominated by work focusing on a set of just seven *E. coli* phages (T1 to T7). While this reductionist approach became a powerful motor for the development of molecular biology, it introduced a bias: all selected phages belonged to the group of virulent phages. Virulent phages are maintained in nature by an uninterrupted chain of bacterial infection cycles. Furthermore, phage infection was investigated under optimized *E. coli* growth in planktonic culture. We know now that slow and unproductive phage replication dominate natural systems, where phages have to deal with bacteria which spent most of their time under limited nutrient conditions. In addition, most bacteria in natural ecosystems grow in biofilms while all model type phages were grown under planktonic growth conditions. Only recently,

Fig. 1 *Streptococcus thermophilus* phage Sfi21: lytic infection versus lysogeny. (A) Phage Sfi21, a Moineauvirus, is a lambda-like tailed phage of the Siphoviridae family. Negative staining electron microscopy (EM). Size bar: 50 nm. (B) An EM thin section shows phage Sfi21 adsorbed to its bacterial host cell. Size bars in B–D: 200 nm. (C) Lytic infection results in the production of progeny phage in the cytoplasm of the infected cell followed by the lysis of the cell. (D) Alternatively, phage Sfi21 integrates its DNA as a prophage into the bacterial chromosome leading to a lysogenic cell with normal morphology and growth properties. The prophage co-exists with the lysogenic cell until induction results into a new lytic phage replication cycle. *Source:* Canchaya, C., Fournous, G., Chibani-Chennoufi, S., Dillmann, M.L., Brüssow, H., 2003. Phage as agents of lateral gene transfer. *Current Opinion in Microbiology* 6 (4), 417–424.

medical microbiologists have started to explore phages infecting biofilms and discovered that filamentous *Pseudomonas* phages actively structured biofilms in the lung of cystic fibrosis patients. Marine microbiologists discovered that phages directly isolated from the ocean have broader host ranges than phages adapted to laboratory growth, changing an important life history parameter of phage-host interaction for ecological and evolutionary considerations.

Synergistic Phage-Bacterium Relationships

Different aspects of phage-bacterium evolution were revealed with the introduction of *E. coli* phage lambda into phage research in the 1950s. Phage lambda is the prototype of temperate phages. Temperate phages, when infecting a cell, have a choice between two life styles. Either they go into a productive replication cycle like any virulent phage, producing progeny phages and killing the host bacterium, or they integrate their phage DNA as a prophage into the bacterial chromosome, creating a lysogenic cell. The prophage remains, except for the phage repressor, transcriptionally largely silent. Prophages then replicate passively with the bacterial DNA until they receive signals from the host bacterium or the environment that induce the prophage into another lytic phage replication cycle, leading to the death of the bacterial host. This peculiar lifestyle has interesting evolutionary consequences: when phage DNA becomes integrated into the bacterial DNA, the prophage DNA is submitted to the selective forces working on bacterial fitness. One might suspect that prophages are a burden to the bacterial cell since they represent a time bomb that can cause the cell to explode at any time. In addition, when phage lambda integrates into the *E. coli* chromosome, it increases the bacterial genome size by about 1% causing supplementary metabolic costs during DNA replication. One percent more DNA to synthesize might not seem like a large metabolic load, but in some pathogenic *E. coli* strains up to 18 prophages are integrated into

the chromosome, representing 18% of the total bacterial DNA. However, this metabolic cost has not been demonstrated. In fact, in competition experiments, lysogens frequently won over isogenic non-lysogens suggesting that the possession of phages represents a selective advantage for the bacterial cell.

Bacteria, which contain prophage(s) encoding fitness factors useful for the host, will be positively selected, and some prophage genes are of obvious use for a lysogenic bacterium. The phage repressor, which is constitutively transcribed from the lysogenic state in order to prevent prophage induction, also prevents related phages from superinfecting the lysogenic cell (homo-immunity). In addition, many prophages express superinfection immunity genes active against other classes of phages, which prevent superinfection by heterologous phages (hetero-immunity). At the same time, these prophage functions protect the lysogen from phage infection and lysis, not a small selective advantage in a phage-infested environment. However, the advantage of being a lysogen goes beyond this protection against phage infection. Data from the 1970s showed that *E. coli* lysogenic with phage lambda displayed a marked growth advantage over non-lysogenic isogenic cells when grown *in vitro* under carbon-limited conditions. This physiological advantage was attributed to the lambda *rex* gene, which is involved in phage superinfection control by decreasing macromolecule synthesis. This growth advantage was also observed in *E. coli* lysogenic with temperate phages P1, P2 and Mu. Lambda lysogens also showed growth advantages over non-lysogenic *E. coli* in animal infection models and the effects were attributed to the lambda *bor* gene, which encodes a membrane protein that confers increased serum resistance to lysogenic *E. coli*.

Phage lambda is in that respect certainly not an exception, as similar experimental data was obtained for *Pseudomonas aeruginosa* and *Salmonella enterica* prophages suggesting that these prophages confer a selective advantage in animal infection models for lysogens over their isogenic non-lysogen counterparts (Fig. 2). Comparative prophage genomics provided additional evidence: a notable observation in phage genomics – both for temperate and virulent phages – is the possession of many hypothetical genes that are non-essential for *in vitro* phage replication. One might speculate that these viral genes encode accessory functions, assisting phage replication under limiting growth conditions. In the case of a prophage these (under *in vitro* conditions non-essential) genes might encode useful functions for the lysogen under certain physiological growth conditions. Selective forces will maintain these “non-essential” genes since they will increase both prophage and lysogen frequency in the bacterial population under stress conditions, which bacteria experience in their natural niche most of the time.

Bacteria profit from phages using them as efficient gene transfer particles for shuttling bacterial genes. Upon induction, the integrated prophage DNA excises from the bacterial chromosome. Occasionally, a faulty excision process leads to the incorporation of bacterial genes positioned adjacent to the attachment sites. These bacterial genes then become incorporated into the phage particle and are subsequently transferred to the next infected bacterial cell. For phages that integrate into specific bacterial chromosomal sites, only few bacterial genes are transferred (specialized transduction, such as for phage lambda). Transfer of bacterial genes is increased by Mu-like temperate phages that integrate randomly into the bacterial chromosome and package random bacterial genes into phage particles. Phages with a headful *pac*-site packaging mechanism can erroneously incorporate bacterial instead of phage DNA into phage capsids, thus transferring larger pieces of bacterial DNA to the next host (generalized transduction).

Recently, a very efficient form of bacterial gene transfer by phages was demonstrated in *S. aureus*. Several *pac*-site *S. aureus* prophages were induced into phage DNA replication while still being integrated in the bacterial genome, i.e., before excision of the prophage DNA. This led not only to an amplification of bacterial DNA surrounding the integrated prophage, but also to a sequential packaging of headful pieces of this amplified DNA into empty phage particles mediated by the phage terminase. In this way bacterial DNA placed up to seven genome equivalents away from the integrated prophage corresponding to several hundred kb of bacterial DNA could be efficiently transferred by transduction into recipient cells. The researchers called this prophage-initiated process lateral transduction, which was 1000-fold more efficient than generalized transduction achieved by infecting the cells with the same phages. Since *S. aureus* is frequently polylysogenic with several prophages scattered around the bacterial chromosome, lateral transfer could be a very efficient way for horizontal gene transfer of bacterial DNA from many chromosomal locations including *S. aureus* pathogenicity islands (SaPIs). Lateral transduction when confirmed with *pac*-site prophages in other bacterial systems could represent a highly efficient motor for horizontal gene transfer.

Phages are ideal gene transfer particles: the tightly knit capsid protects the incorporated DNA from physicochemical damage in the environment and the phage tail structures assure the recognition of target cells and the efficient injection of the DNA into the new host. In *S. aureus*, intricate interactions between pathogenicity islands and helper phages mediate virulence gene transfer. As long as the recognition process is limited to the same bacterial host species, phages mobilize bacterial DNA only within a given bacterial species. Under individually rare, but cumulatively sufficiently frequent, conditions, phages can infect across the bacterial species and genus borders and can also mediate cross-species or wider gene transfer. Phage-mediated gene transfer from *S. aureus* to *Listeria* was also experimentally demonstrated. The potential breadth of gene transfer across bacterial lineages is also suggested by the distinct GC-content of some extra phage genes – suggesting transfer from bacteria with different GC content – while the remainder of the phage genome shares the GC content of the bacterial host reflecting codon adaptation. This extra or more DNA in phages was dubbed “moron”, and it is found at specific places of phage genomes and frequently contains its own promoter and terminator to allow transcription during the lysogenic state. In this way, the lysogenic cell can acquire a new genetic trait (phenotype) compared to the parental non-lysogenic cell, leading to lysogenic gene conversion (LGC) after the incorporation of a new prophage.

Prophages can also lead to phenotypic changes of the lysogen by integrating into a host gene and inactivating it. Phages like Mu integrate randomly into the bacterial chromosome and phage Mu replication proceeds by further random copy-paste events into the bacterial chromosome mediated by the phage transposase. By this process, many bacterial genes can be inactivated, and mutant bacteria are created – in fact, the phage Mu derives its name from this mutational activity. Gene inactivation can be an adaptive process: in the medical literature cases are documented where the loss of specific bacterial genes is important for the

Prophage genes that affect *Salmonella* / *E. coli* virulence in the mouse model

Fig. 2 *Salmonella* / *Escherichia coli*: Prophage genes that affect the virulence of the lysogen in mouse models. Gene maps of *Salmonella enterica* serovar Typhimurium prophages Gifsy-1 and Gifsy-2 were aligned with *E. coli* phage lambda. Sequence-related genes were linked by pink shading. The GC scan for phage lambda suggests distinct origins for the left and right arm of the lambda chromosome. The phage modules are color-coded: Lysogeny, red; DNA replication, orange; regulation, yellow; lysis, pink; head morphogenesis, green; head-tail-joining, brown; tail, blue; tail fiber, mauve; virulence, black (circled and annotated). Source: Canchaya, C., Fournous, G., Chibani-Chennoufi, S., Dillmann, M.L., Brüssow, H., 2003. Phage as agents of lateral gene transfer. *Current Opinion in Microbiology* 6 (4), 417–424.

development of a pathogen (e.g., *Shigella*). Phage Mu also encodes an invertase that inverts the orientation of a phage tail fiber gene to extend the host range of Mu. Such an invertase might also be of use for inverting adjacent bacterial genes. Inversions of large bacterial chromosomal segments were conspicuously flanked by prophage sequences (*Streptococcus pyogenes*, *Xylella fastidiosa*, *E. coli*, *Bartonella*). Therefore, prophage sequences might here have served as cross-over sites for phage or cellular recombination enzymes. In *Bartonella*, chromosome inversions might permit temperature adaptations to the human-flea host change.

Interest in phage-mediated gene transfer grew substantially when bacterial genomics and phylogenetic analyses revealed strong elements of horizontal evolution overlaying and frequently obscuring the vertical evolution of bacteria along a classical phylogenetic tree. Phages belong to mobile DNA elements that accelerate bacterial evolution by allowing rampant horizontal gene transfer. Comparative bacterial genomics showed that beyond the bacterial core genome (shared by most bacteria within a given bacterial species), the accessory bacterial genes (found only in some bacterial isolates from this species) comprised a large proportion of mobile DNA, and particularly of prophage DNA. Phage DNA transfer might thus represent a motor for bacterial evolution only comparable, if not superior to, the role of sexual reproduction in the evolution of higher organisms (Fig. 3).

It seems that the transfer of lysogenic conversion genes (LCGs) by prophages has played a particularly prominent role in the evolution of bacterial pathogens. One can even argue that prophages made certain bacteria pathogens (e.g., *Streptococcus pyogenes* (Figs. 4–6), *Staphylococcus aureus*, *Vibrio cholerae*, *Clostridium botulinum*).

This predilection of phages for pathogens might be explained by their evolutionary history. In early evolution, prokaryotes experienced predation only from prokaryotic viruses. When protists evolved, many eukaryotic cells and small metazoa made a living by grazing on bacteria. Bacteria were thus trapped between two predators. In a stone-scissor-paper game some bacteria might have teamed up with phages that had carried toxin genes. Toxin-producing lysogenic bacteria could thus kill protists that engulfed them. The killed predator released a lot of nutrients, which then fed the former prey, i.e., the lysogenic bacterium, furthering their abundance in the population. When protists evolved into animals, existing lower animals like sponges repurposed bacteria-eating amebocytes as defense systems to protect them from microbial invasion. This primitive cellular immune system evolved into phagocytes patrolling the bodies of higher animals to engulf and eliminate bacterial invaders. The coalition between bacteria and temperate phages could once again pay off when bacteria explored the life style of exploiting animals as a food source evolving either as commensals or pathogens. This hypothesis could explain why a frequent scheme of bacterial pathogenesis is the survival of bacterial pathogens in phagocytes (the functional followers of sponge's amebocytes in animals), why a significant proportion of bacterial pathogens have prophage-encoded virulence genes, and why some virulence factors from animal pathogens are still active against unicellular eukaryotes. In the stone-scissor-paper game other alliances are possible and they are apparently realized. There is increasing evidence that phages have a major impact on the composition and dynamics of the gut microbiota and since the latter are thought to exert a major impact on the health of the animal host, phages might also indirectly impact on human health. Indeed, phages were proposed as an infectious layer in the mucus overlaying the gut epithelia protecting the human body together with secretory immunoglobulins against pathogen invasion. Notably, some phages display immunoglobulin-like folds in their capsid proteins, which might be responsible for interaction of phages with the mammalian immune system and mucus glycoproteins.

Phage-bacterium interactions have many other evolutionary facets. For example, virulent phages from cyanobacteria encode important genes for the photosynthetic apparatus. Their adaptive value might be providing extra energy to the infected cell by replacing readily bleached components of the photosystem in order to maintain a high ATP level that favors phage replication. The nonsystematic phylogenetic distribution of photosynthetic capacity in bacteria suggests a role for horizontal gene transfer in the evolution of bacterial photosynthesis, possibly mediated by phages. If confirmed, phages could have contributed to the spread of one of the major inventions in the evolution of life on earth.

Lysis-Lysogeny Decision: An Ecophysiological Perspective

The classical phage lambda attracted researchers for its lytic-lysogenic lifestyle decision. Spontaneous prophage induction had traditionally been explained as a stochastic process under the influence of biochemical noise. The dramatic cell-to-cell variation in phage burst size demonstrated in the classical fluctuation test was used as an argument for such an interpretation. Instead of the non-deterministic approach to this life style decision, microbiologists, who exploited state of the art single cell analytical methods, now started to unravel the hidden variables driving this decision outcome. This analysis demonstrated large cell-to-cell variation in the transcription and protein expression of the lambda CI repressor that correlated with the switch to lysis decision. Phage infection is now also morphologically investigated at single cell resolution, demonstrating new layers of complexity, such as the location and migration of the phage on the cell surface and the interaction of the injected phage DNA with the chromosomal bacterial DNA.

An interesting recent model, dubbed the “Piggyback-the-Winner” model, proposed that lysogeny predominates at high microbial abundance and high bacterial growth rate. This conclusion was based on metagenomic virome data analyses from coral ecosystems and a meta-analysis of published viral and microbial densities in various ecosystems. It provides an opposing view to the “Killing-the-Winner” model of phage infection and challenges the classical observations where cell starvation – indicating low nutrient availability and thus low chances for lytic propagation – predicts lysogeny to become the preferred strategy. Current data indicates that the number of infecting phages, the volume of the infected cell and the position of the phage on the infected cell surface, influence the infection outcome with phage lambda. For a *Bacillus* phage, a phage-encoded system resembling quorum sensing mechanisms was described and called “arbitrium” system. It consists of a 6 amino acid peptide, an intracellular peptide

receptor and a negative regulator of lysogeny, all encoded by the *Bacillus* phage. This system allows phage-to-phage communication facilitating the best replication strategy. Such observations will pave the way to a sociobiology of phages.

There is also some evidence that lysogeny could become “autocatalytic” within a given cell population. *Salmonella enterica* frequently contains multiple and replication-competent prophages. If such lysogenic cells are mixed with non-lysogenic *S. enterica* cells, spontaneously induced prophages will kill a few lysogens and infect and kill susceptible non-lysogenic *S. enterica* until some become also a lysogen and thus resist further lytic infection. In this way, lysogenic cells can become the dominant bacterial population, at least under *in vitro* conditions. The prophage behaves here as a typical selfish genetic element. Prophages have also recruited genetic elements that stabilize them against deletion. A typical case is the toxin-antitoxin gene cassette. It expresses a longer-lived lethal cell toxin that is neutralized by a shorter-lived antitoxin. Should the cell delete the prophage, it runs out of the antitoxin and will be killed by the persisting toxin. The prophage is thus protected against its loss. However, *in vivo*, the situation is frequently more complicated, and a prophage can become a burden. For example, in the nose *Streptococcus pneumoniae* produces H₂O₂ as a chemical weapon against competing bacteria. This peroxide induces prophages in *Staphylococcus aureus*, killing not only the lysogen but, via the induced prophage, also killing susceptible non-lysogenic *S. aureus*. In nature the phage-bacterium interaction is therefore much more complicated due to a multitude of phage-bacterium, bacterium-bacterium, phage-phage and last, but not least, bacterium-host interactions, which we are just beginning to study in the human gut microbiome and the phyllosphere (the microbiome around plants is even more complex in the soil environment). In these data sets, we see the impact of phages on bacteria through the magnifying glass of ecophysiology.

Coevolution: Polylysogeny

The impact of phages on bacterial evolution can be studied by analyzing the footprints of evolution and selection left in bacterial genome sequences. The survey of 58 *E. coli* and 27 *S. enterica* genomes revealed a mean of 8.2 and 5.6 prophages per bacterial genome, respectively. Polylysogeny, the possession of multiple prophages, documents the possibility of the coexistence of different phages despite the phage-encoded superinfection exclusion mechanisms. This creates complex interactions between prophages within a lysogen: one prophage can for example inhibit the excision of another prophage as seen in *Enterococcus*. Polylysogeny also has interesting consequences for the bacterial cell. In this way, different combinations of lysogenic conversion genes provided by distinct prophages can be combined allowing combinatorial associations of different phage-encoded fitness factors, thus creating a much greater genotypic and phenotypic diversity in poly-lysogens. This permutation principle is actually exploited by several bacterial pathogens. For example, in *S. aureus* variable prophage combinations in polylysogens allow the exploration of different combinations of phage-encoded superantigens to flexibly distract the immune system of the host. In *S. pyogenes*, various combinations of prophages contribute to an astonishingly wide spectrum of clinical disease manifestations. Polylysogeny in *S. pyogenes* thus facilitates the rapid evolution of new pathogenic traits within a decade, as demonstrated by “flesh eating” infections (*S. pyogenes* fasciitis), or the changing epidemiology of scarlet fever depending on the prevalence of the toxin-encoding prophage in the bacterial population. In *Vibrio cholerae*, the cholera toxin is prophage-encoded, and the pathogenicity of this bacterium is the result of a complex physical interaction between three phages.

Coevolution: Prophage Remnants

In the case of the 58 *E. coli* and 27 *Salmonella* genomes most prophages could be attributed to lambdoid phages (59%) followed by P2-like phages (13%). However, this is not a general pattern: *Pseudomonas aeruginosa*, a more distant relative of these bacteria, showed a substantial contribution of additional temperate phages like Mu-like phages and filamentous phages. Filamentous phages cause chronic non-lytic infections in *E. coli*, but do not integrate into the bacterial chromosome because they lack an integrase. In *V. cholerae* filamentous phages have recruited bacterial enzymes for chromosomal integration, while in *Pseudomonas* filamentous phages encode a integrase/recombinase in the small phage genome, possibly explaining the high prevalence of lysogeny with these phages in *P. aeruginosa*.

In the 58 sequenced *E. coli* strains, the genome size of lambdoid prophages was bimodal with a major peak at 40–50 kb genome size corresponding to that of infectious extracellular lambdoid phages and a second peak at about 10 kb. The latter was interpreted as defective lambdoid prophages. The large infectious prophages probably represent recently integrated prophage DNA, while the small

Prophage DNA determines strain specificity

Fig. 5 *S. pyogenes*: Prophage DNA determines strain specificity. Genome alignment of two *S. pyogenes* strains belonging to different M types. Gaps in the alignment (blue circles) correspond to prophage DNA (red rectangles) that are either missing in one strain or the other or are found at a different genome position. Modified from Boyd, E.F., Brüssow, H., 2002. Common themes among bacteriophage-encoded virulence factors and diversity among the bacteriophages involved. *Trends in Microbiology* 10 (11), 521–529.

prophages were interpreted as remnants from initially complete prophage genomes created by a rapid viral DNA deletion, suggestive of a prophage domestication process. This prophage reduction process was interpreted as a consequence of the trend to maintain a small given genome size in bacteria. If such prophage reduction mechanisms did not exist, bacterial genomes would over evolutionary time periods be overrun by selfish DNA invasion (something what seems to have happened in higher plants and animals). However, this deletion process does not seem to be random. Some directionality seems to apply (integrases and repressor genes appear to be

Fig. 6 *S. pyogenes*: Prophage DNA determines bacterial virulence profile. Prophages from *S. pyogenes* encode many potential virulence factors. Left: Prophages are visualized as red boxes on the circular genome maps of four sequenced *S. pyogenes* strains representing three different M types. Right: Prophage genes near the prophage *attR*. Genes of the lysis module are colored in mauve; candidate lysogenic conversion genes are colored in red and are annotated: mf, mitogenic factor; sdn, streptodornase; sla, streptococcal phospholipase A₂; spe, streptococcal pyogenic exotoxins, ssa, streptococcal superantigen. enriched in prophage remnants) and phage genes of selective value to the bacterial host are likely to be conserved. When lysogens and non-lysogens were competing, the lysogen frequently outpaced the non-lysogen, suggesting a strong selective advantage, and this observation also applies to prophage remnants. Indeed, some prophage remnants of *E. coli* K12 have a long evolutionary history and it was experimentally demonstrated that they confer help in stress situations like acid or oxygen exposure, or help in coping with the stress of antibiotic exposure or in biofilm growth. In line with the selective value of these prophage remnants, the purge of non-synonymous mutations in these elements suggests that evolution tries to maintain the gene function in these remaining prophage genes. Genes from defective prophages thus contribute to the fitness of the bacterial hosts well beyond the known phenomena where isolated phage tail structures serve as bacteriocins, or phage capsids evolved into gene transfer agents.

Coevolution: Integration Sites

The coevolution of bacteria and their phages is also documented by the integration sites of temperate coliphages. Prophages integrate into conserved hotspots of the *E. coli* chromosome and frequently target intergenic regions to avoid interference with bacterial gene expression. Prophages are also inserting non-randomly with respect to the large-scale bacterial chromosome organization: when plotting prophage integration sites on the circular *E. coli* chromosome, a clearly increasing origin-to-terminus gradient of integration sites was observed. Prophage integration into the highly expressed genes around the origin of replication

would lower bacterial fitness and are thus counterselected. A possible solution to this interference problem is provided by temperate phages that maintain their genome as an extrachromosomal DNA and assure their maintenance by a toxin-antitoxin gene system like coliphage P1. This extrachromosomal phage lifestyle was considered to be rare, but recent data from *S. aureus* showed that extrachromosomal phage DNA in latently infected cells is more prevalent than initially thought. However, prophages do not always avoid integrating into actively transcribed regions, resulting in gene inactivation with deleterious effects if important genes are disrupted. Recently, it was proposed that such inactivating prophage integration can also be used as a regulatory switch where transcription resumes when the prophage is excised into an episomal stage without leading to cell lysis. This “active lysogeny” might come into play when commensal or pathogenic bacterial cells receive signaling molecules within animal cells (phagocytosis) or in animal hosts (gut). Prophages might also sometimes lead to large scale chromosomal rearrangements when either cellular RecA-like or phage-encoded Rad52-like enzymes mediate recombination across two prophages sharing some sequence identity, but located in distinct chromosomal sites.

Coevolution: In the Patient

Coevolution between phages and bacteria is not only seen from comparative genomics, highly dynamic phage-bacterium relationship changes were also documented over much shorter time periods. In microcosm laboratory experiments *Pseudomonas fluorescens* evolving under phage pressure showed an increased mutation rate and evolved greater genome wide divergence particularly over the LPS gene cluster, the receptor of many phages. The evolved bacteria showed also greater fitness when tested in the absence of phages against the original strain. In *S. pyogenes* a phage integrates into the DNA mismatch repair genes *mutS-mutL*, increasing the mutation rate of the bacterium 200-fold. The cell uses this phage integration as a molecular switch, since the prophage is excised at low cell density restoring normal mutation rates. Short term phage-induced evolution was also seen in cholera patients that showed, in addition to *V. cholerae*, also a vibriophage in the stool. Bacterial colonies isolated from individual cholera patients were practically all resistant to this vibriophage and isogenic to the infecting strain except for mutations in an outer membrane porin and a ToxR signaling protein, which activates virulence gene expression under host environmental stimuli. These ToxR mutants were attenuated in mouse infection model. Apparently, *V. cholerae* evolves under phage pressure to lesser virulence in the later course of human cholera infection. Notably, evolution of the cholera pathogenicity was also described over the course of an individual cholera outbreak and also linked to an increase in phage prevalence. The development of significant environmental phage titer might actually end a cholera season.

Other instructive examples are provided by comparing *S. aureus* colonizing the nose of healthy subjects or the lungs of cystic fibrosis patients. The frequency of genome alterations was significantly higher in the patients than in the controls. In nearly half of the patients, the genome alterations were linked to prophage mobilization, mostly by integration into a single bacterial gene. Phage translocation in the patients leads to a splitting of the bacterial population into various subtypes differing in virulence gene composition, each of which might have different selective advantages for the pathogen in the patient. Phage mobilization seems to be induced by the frequent antibiotic treatment in the patients.

Coevolution: Defense Mechanisms

Coevolution of phages and bacteria is perhaps best documented by the analysis of bacterial defense mechanisms against phages and the countermeasures of phages against this control. This genetic arms race is apparently a major driver of both bacterial and phage evolution. Bacteria use several anti-phage strategies (receptor modification preventing phage adsorption; restriction-modification systems destroying invading phage DNA; abortive infection mechanisms, where a variety of seemingly altruistic cell death processes block phage replication). The latest addition in discovery, but not in evolutionary antiquity is the bacterial CRISPR-Cas system. All these anti-phage systems are characterized by a stunning genetic diversity on the bacterial side (LPS, R-M, *abi*, CRISPR-Cas diversity), illustrating the difficulty to solve the challenge posed by phages. The reason is of course the mutability of the phages, which evolved counter-mechanisms against any of the bacterial defense mechanisms. The details of this arms race can be astonishingly multi-layered. To illustrate this with two examples: phages can escape the control of the CRISPR-Cas system by acquiring point mutations in regions of their genomes that match spacer sequences. Bacteria can then “update” the CRISPR-Cas system by incorporating modified spacers. Molecularly more complex are anti-CRISPR genes located in a specific genome region of Mu-like *Pseudomonas* phages encoding a large variety of small phage proteins inhibiting this bacterial anti-phage system. The diversity of mechanistic action of these anti-anti-phage proteins might be a mirror image of the stunning molecular diversity of CRISPR-Cas systems in some bacteria. A bacterial anti-anti-phage device is suspected in this system but was already demonstrated in another anti-phage system. In order to escape R-M system control phages were selected that either avoid restriction sites or modify their bases: in coliphage T4 cytosine gets a hydroxymethyl addition or a further glycosyl derivation, preventing their recognition by restriction enzymes. *E. coli* evolved restriction enzymes, e.g., GmrSD, that can cleave these modified bases. T4 evolved the internal capsid protein ISI*, which is co-injected with phage DNA, binds and inhibits GmrSD. *E. coli* evolved a GmrSD variant that resists ISI* binding. Furthermore, mutant T4 exist that escape this GmrSD variant. This tit-for-tat aspect seems to be a characteristic of the bacterial-phage coevolution in a never-ending process.

Coevolution: War and Peace

Antagonistic scenarios were observed with a single phage and bacterium in chemostats and depending on the specific coliphage used, different outcomes were described, but phages often lost the race. However, this *in vitro* context excludes external factors (competition from other bacteria, cost of resistance development for bacteria, genetic support from other phages), which will strongly impact the outcome of such a race in nature. In fact, one might even speculate that the balance of selective forces for this battle favors not the supremacy of one or the other partner of this coevolution game, but both work as drivers of their coevolution. Phages are challengers that keep bacteria under pressure to evolve, but phages have no selective interest in winning this race against bacteria. Since phages depend on the bacterial cytoplasm for their replication, this would be a Pyrrhic victory culminating in the phage's extinction. A truce is not possible for a phage as an infectious agent as it must lyse a cell to be retained in evolution. Lysogeny is in some way an escape lane for peaceful coexistence, but it has its limits. In *E. coli* so far, an upper limit of about 20 prophages was described in isolates with a moderately expanded genome size. Even in *Pseudomonas*, which sports with 6 Mb, an unusual large bacterial genome, relaxing control via CRISPR-Cas and R-M systems was only associated with a 300 kb increase in genome size. There are apparently mechanisms that maintain small genome sizes in bacteria, preventing the accumulation of viral-like DNA sequences in the host genome, in contrast to higher animals and plants with retrovirus-like elements where genome sizes are wide-ranging and apparently uncorrelated with organismal complexity as described by the classical C-value paradox. While bacteria could theoretically win the arms race with phages, there is apparently no incentive to eliminate phages. Literature data consistently demonstrates that prophages are of selective value for bacteria, driving phages to extinction in a given bacterial group might compromise their competitiveness in their ecological niche. This argument can be easily extended to lytic phages as a motor for accelerated evolution of bacteria allowing lateral gene transfer by generalized phage transduction and phage-derived gene transfer agents. It thus seems that the paradoxical inefficiency of both bacterial phage-defense systems and phage anti-defense systems have an inborn limitation allowing some, but deliberately not total control of the other player in this coevolution game. The role of phages in bacterial evolution is thus likely to be enormous and will be complemented by other mobile genetic elements to fuel lateral gene transfer in bacteria. Since phages in contrast to plasmids, transposons, insertion elements and the like kill the bacterial cell, phages might play a unique role in bacterial evolution. There are differences with respect to what fitness factors are contributed to bacteria by mobile DNA. While plasmids and transposons are privileged carriers of antibiotic resistance genes (ARG), phages are privileged carriers of virulence genes. There is conflicting data on how frequently phages carry ARG: metagenome data demonstrated a substantial load of ARG in the virome fraction particularly after antibiotic treatment of the host, while the genomes of cultivated phage rarely show ARG. The data are not necessarily mutually exclusive, but phage genomes only rarely contain biologically proven ARG. Whatever the outcome of this controversy, phages that were in the past commonly depicted as parasites of bacteria have with recent research transmogrified into, albeit difficult, partners of bacteria, and necessary elements for diversity in bacterial ecology and evolution.

Glossary

Agro-terrorism A subset of bioterrorism, defined as the deliberate introduction of animal or plant pests (e.g., bacteria, viruses, fungi) with the goal of generating fear, causing economic damage, and/or undermining social stability (Keremidis *et al.*, 2013).

Bio-crime The threat or use of a biological agent for murder, extortion, or revenge (Carus, 2002).

Biological warfare (synonymous with biowarfare)

A specialized type of warfare involving the use of biological

agents conducted by a government against a target (human, agriculture, or infrastructure) (Carus, 2002).

Bioterrorism The threat or use of a biological agent (or toxin) against humans, animals, or plants by individuals or groups motivated by political, religious, ecological, or other ideological objectives (Carus, 2002).

Weapons of mass destruction Weapons that can destroy entire cities, regions, etc. (Merriam-Webster dictionary).

Introduction

The idea of using non-traditional weapons for offensive purposes is not new. Using chemical and biological agents as well as toxins to win wars has a long history. These agents and toxins have also been used by various groups such as military personnel, and governments or non-governmental organizations against civilians and individuals to incapacitate or cause terror in a population. In addition to the use of these weapons against people, another target of these agents and toxins is agriculture, which can trigger severe economic and societal repercussions. Not all utilization of these agents and toxins was to cause destruction; these agents have also been used with the intent of benefitting society, agriculture, or the environment by biologically controlling pests. Whatever the target, intention, and mode of introduction of these agents and toxins, the effects can be long lasting and devastating, as can be shown by several instances of intentional and natural introductions of these agents.

Unconventional Bioweapons

Venomous animals, poisonous plants, and toxins have been used over the centuries as offensive weapons. A common goal of these attacks is often to inhibit or reduce the enemy's ability and capacity to fight. These objectives could be met by killing enemy combatants, incapacitating them through illness, or denying them access to needed resources such as a water supply. The association between illness and fatalities from toxins, primarily through the consumption of poisonous plants, or from the bite or sting of venomous animals or insects must have been obvious long ago. The ability to use these methods to kill on an individual or large scale, such as an army, was used very early in our history. For example, poison could be used to enhance a weapon's immediate effectiveness by adding it to the tip of arrows. Poison is also useful for killing an enemy from a safe distance, in terms of both space and time. Poisoning water supplies, such as wells, has been an effective offensive tactic since as early as the 6th century BC when the fungus, ergot, which grows on rye and other grasses, was used by Assyrians to poison wells of their enemies (Bradley and Sustaita, 2013). Another example of this took place in 600 BCE when roots of hellebore, a poisonous flowering plant in the buttercup family (Romano Jr. 2007), were added to the water supplies to cause diarrhea in the enemies of Solon of Athens. Later, the Romans used the carcasses of dead people and animals to poison water sources used by their enemies (Florus, 1852; Lesho, 1998). In 190 BCE, Hannibal developed another unconventional bioweapon which consisted of pots filled with venomous snakes (Campbell, 2014). These pots were successfully used by launching them onto enemy ships during a naval battle causing the sailors to fight on two "fronts", the snakes and the invading sailors (Nepos, 2015).

Use of Diseases in Early History

Humans began using weapons for what we now consider biological warfare long before they knew what the toxins were or the etiologic agents for any of the diseases. Even without the detailed information that we now have on various disease-causing agents, people were able to use these agents, which spread from one person to another, for offensive goals. Bacterial diseases such as plague and viral diseases such as smallpox were notable for their potential use against an enemy because of their rapid spread and severity.

Widespread and devastating outbreaks of plague occurred unintentionally during warfare as a result of troop movements. This may have been the catalyst for the idea of using plague as a bioweapon. In much the same way as the spear-head dipped in poison enhanced the arrow, the use of the catapult combined with disease causing agents, was used to enhance siege weapons. The development of relatively long-range siege weapons, such as the catapult, enabled armies to use the catapult and plague infected bodies to improve the devastating outcome of their weapons. Bodies of victims who died of plague were placed on the catapult and flung into enemy strongholds and cities where, it was hoped, an outbreak would occur. This effective tactic was first used by the Mongols during their conquest of Asia and Europe in the 14th Century (Wheelis, 2002) and was perhaps last used by Peter the Great in the 1700s (Riedel, 2004). This tactic was also used to spread smallpox into cities under siege.

Spread of smallpox has been used throughout the centuries to kill enemies and civilians, even though it has been only since the end of the 19th Century that we recognized viruses as disease causing agents (MacLachlan, 2017). The highly infectious disease, smallpox, is caused by the virus *Variola major*. It is an ideal bioweapon and is perhaps the viral equivalent of plague. The virus is easily spread from an infected person to a susceptible person via aerosols. Once the person becomes infected, they are highly likely to become sick and suffer a greater than 30% chance of dying from the disease. In addition to the high morbidity and mortality rates, the disease causes fearful symptoms which add to the population's terror. This virus had a devastating effect on the indigenous population when the Spanish conquistadors came to the New World in the 16th century. The dissemination of smallpox by the arrival of approximately 300 conquistadors caused the deaths of about 90% of the indigenous population within a relatively short period of time.

The intentional use of smallpox against an enemy occurred about 150 years later when one of the commanders of British forces fighting in "Pontiac's Conspiracy", General Sir Jeffrey Amherst, suggested the distribution of smallpox-contaminated blankets to an unsuspecting coalition of Indians in 1763 (Eitzen Jr and Takafuji, 1997; Patterson and Runge, 2002). Because of the obvious advantages of using smallpox against an enemy, smallpox was again used as a bioweapon to cause the spread of disease during the American Revolutionary War (Hopkins, 1983; Meyer and Morse, 2016).

20th Century State Sponsored Biological Weapons Programs

Although the use of gas or poisonous smoke was first developed in China in approximately 400 BCE (Mayor, 2008) it was not until the First World War that gas was used on a large scale to clear enemy trenches (Fitzgerald, 2008). From 1914 to the end of the war in 1918 there was a substantial increase in the use of unconventional weapons, with primarily chemical weapons being the unconventional weapons of choice. These chemical weapons included tear gas, chlorine, phosgene, and mustard gas. There are limited reports of the use of biological weapons during this time period; however, one example cited is Germany's operation to use biological weapons to spread the bacteria which causes glanders amongst Allied Army horses and mules (Eitzen Jr and Takafuji, 1997; Kettle and Nicoletti, 2014).

Horror from the use of these weapons was realized after the end of the First World War and in 1925, the Geneva Protocol was signed to prohibit the use in war of "asphyxiating, poisonous or other gases and of bacterial methods of warfare" (UNODA, 2019). In addition to not addressing the use of viruses as weapons, another major drawback of this protocol was that it did not forbid the "production, storage, testing and transfer" of these weapons, nor did it prohibit the use of these weapons for retaliation if a country were to be attacked using chemical or bacterial weapons. Even though the Geneva Protocol had obvious shortcomings, it was an important first step by various nations to address the need to control these weapons.

The 1925 Geneva Protocol did not stop the use of state sponsored biological weapons development in every country. From 1932–1945, around the time of the Second World War, Japan developed a sophisticated biological weapons program that included bacterial and viral pathogens including: plague, anthrax, smallpox, and yellow fever (Riedel, 2004). Some of these weapons were tested on thousands of people in Japanese-occupied China (Eitzen Jr and Takafuji, 1997). Although viruses were used for these experiments, the methods needed to propagate viruses on a relatively large scale and the ability to preserve infectivity for weaponization was not well developed at this time. Therefore, bacterial agents were predominately used as bioweapons through the early 20th Century.

Many nations began to study biological weapons in order to defend against them and to use them in retaliation, if needed. During the time around the Second World War and into the Cold War there were at least 11 countries that developed state-supported offensive biological weapons programs. The countries with offensive weapons programs included: Canada, France, Germany, Hungary, Iraq, Japan, Poland, South Africa, Soviet Union, United Kingdom, and the United States (Millett and Snyder-Beattie, 2017).

The United States and the United Kingdom both participated in the study of potential biological agents, and in some cases, they worked on the development of agents that could be used for biological warfare. A U.S. program was considered in 1941 by Secretary for War, H.L. Stimson, headquartered at Camp Detrick, Fredrick, Maryland in 1943. The program was expanded to a production facility in Terre Haute, Indiana and a test center at Dugway, Utah; both established in 1944. In the 1950s, a bioweapons program in the United States primarily focused on toxins and bacterial agents. However, the U.S. was interested in the study of viruses as potential bioweapons. There were a number of different viral agents studied by the U.S. including: Argentine and Bolivian hemorrhagic fever viruses, Hantavirus, Lassa fever, smallpox, yellow fever, and Western equine encephalitis virus. Of these viruses studied, only Venezuelan equine encephalitis virus was thought to be useful for weaponization.

The UK Biological weapons program, began in 1916 and was primarily based at Porton Down (Hammond and Carter, 2002) with Gruinard Island used as a testing site (Roffey, 2002). Due to the contamination on Gruinard Island, it was not declared to be free of anthrax and de-requisitioned until 1990 (Hammond and Carter, 2002). Beginning in 1948, the British also conducted sea

trials in various locations to study pathogen dispersal and viability. Operation Ozone, conducted in the West Indies in 1954, was the first trial to study a virus: Venezuelan equine encephalitis (VEEV), which was obtained from the U.S. Camp Detrick facility. The virus was again used in the 1945–55 Operation Negation, together with Vaccinia virus which was used as a surrogate for smallpox. As part of defensive programs, inhalation experiments with animals at Porton Down, evaluated VEEV and Vaccinia, and also other viruses such as Ebola, influenza, Marburg, Newcastle disease, rabbit pox, Semliki forest, Variola, and Western equine encephalitis.

A much more extensive state funded bioweapons program was developed in the Soviet Union beginning in the 1920s. This program was initially focused on bacteria such as the ones which cause plague, anthrax, tularemia, and glanders (Leitenberg, 2001; Roffey, 2002). In 1999, it was reported that the Soviet program included work on Machupo, Bolivian hemorrhagic fever, Lassa fever, Marburg, Monkey pox, Rift Valley fever, Russian-Spring Summer encephalitis, Venezuelan equine encephalitis, and Variola major viruses (Alibek and Handelman, 1999). Later sources reported that the Soviet Union was studying at least seven viruses including Junin, Ebola, rinderpest, Japanese encephalitis virus, tick-borne encephalitis virus, and African swine fever virus (Meyer and Morse, 2016). Of these seven viruses, the Soviet Union reportedly weaponized at least three of them: Marburg, Venezuelan equine encephalomyelitis, and Variola major.

In 1972, the Biological Weapons Convention was signed and went into effect in 1975. This treaty was signed by many countries including the U.S., the U.K., and the Soviet Union, and restricted countries from developing, producing, stockpiling, or acquiring biological agents, weapons, and equipment outside of peaceful purposes. The U.S. offensive bioweapons program had already been terminated by the time of the signing of this Convention in 1969 (Riedel, 2004). As the U.S. and U.K. began to destroy their stockpiles and ending their programs, the Soviet Union secretly expanded their program by building new facilities and employing large numbers of workers and scientists (Tucker, 1999) including 9000 key scientists and engineers (Alibek and Handelman, 1999; Federation of American Scientists (FAS), 2019). About 10,000 people worked on agricultural pathogens in perhaps six so-called “agricultural research centers”. These facilities had a large production capacity with the estimated production for anthrax being approximately 4500 metric tons per year (Foster, 2003).

In the last years of the 20th century, there were bioweapons programs started by other countries. For example, Iraq began a biological weapons program focused on bacteria, specifically anthrax, and toxins (Atlas, 1999; Eitzen Jr and Takafuji, 1997). There has been a continued proliferation of these agents for offensive purposes by many other countries. The U.S. Congress Office of Technology Assessment concluded in a 1995 report that biological weapons were probably possessed by Bulgaria, China, Cuba, Egypt, India, Iraq, Iran, Israel, Laos, Libya, North Korea, Russia, South Africa, South Korea, Syria, Taiwan, and Vietnam.

Viruses as Bioweapons

In general, there are several characteristics of viruses that enable them to become effective bioweapons. These characteristics include: high morbidity and in some cases mortality, relatively low infective dose, potential for person-to-person transmission, and with appropriate processing, infectivity by aerosol. In some respects, high morbidity is preferable to high mortality, because caring for the sick places a greater demand on resources, infrastructure and support personnel as compared to the demand on resources associated with fatal cases. In contrast with development of what we now call weapons of mass destruction, including conventional explosives, nuclear, and chemical materials, biological agents have several advantageous characteristics. With modern methodologies, they are relatively easy to obtain, inexpensive to produce and relatively easy to deliver. Until recently, they were difficult to detect and identify, where detection relied on the presence and identification of unusual cases by clinicians. Under suitable climatic conditions, viruses can disseminate over large areas and cause large numbers of casualties. The delay from delivery to the onset of infections, would allow the perpetrator to leave the target site to avoid detection, if necessary. It is also possible to vaccinate the aggressor’s troops so that they can occupy the target site even as the agent begins to be transmitted from initial victims to new ones. Genetic engineering could provide a means by which some of the biological agents can be enhanced with respect to infectivity, lethality, and resistance to countermeasures.

With the characteristics of an effective bioweapon in mind, it is easy to see why Variola major virus, the virus that causes smallpox, has remained a significant consideration for use as a bioweapon. It is highly contagious, requires a low inhalation dose, can be spread from person-to-person, has very high morbidity, and a high mortality rate of 30%–40%. The virus can be stored by lyophilization for long periods of time. As demonstrated by the successful eradication campaign, vaccines are highly effective; however, with eradication accomplished, vaccine availability is now limited. Even with stockpiles, genetic engineering could potentially modify a virus intended for bioterrorism to be resistant to the current vaccine. With an incubation period of up to 17 days and lack of clinical expertise, simply because physicians today have never seen a case, a release of the virus could spread quite widely before detection and activation of countermeasures.

The number of viruses that have been considered as bioweapons to be used on a human population is extensive and includes viruses from a number of different virus families, including: *Bunyaviridae* (Rift Valley fever virus and Hantavirus); *Togaviridae* (Venezuelan, Eastern, and Western equine encephalomyelitis viruses and chikungunya virus); *Flaviviridae* (Japanese encephalitis virus, yellow fever virus, dengue virus and tick-borne encephalitis virus); *Arenaviridae* (Lassa fever, Machupo, and Junin viruses); *Filoviridae* (Ebola and Marburg viruses); *Orthomyxoviridae* (Influenza A); and *Poxviridae* (Variola major) (Meyer and Morse, 2016). Although the viruses listed above have been studied for their potential use as bioweapons, few of them have been used as such. Many of the viruses listed above require significant expertise and some require the highest level of biocontainment (biosafety level four (BSL-4)) in order

to work with them safely. This high degree of expertise and biological containment is prohibitive for non-governmental groups to attempt weaponization.

According to calculations by the World Health Organization (WHO) completed in the 1970s, these viruses could cause devastating results if purposely or accidentally released. The WHO examined the possible effects of Rift Valley fever virus (RVFV) and tick-borne encephalitis virus (TBEV) along a 2 km path, upwind of a city with a population of 500,000 and concluded the release of either agent could result in up to 35,000 infections with RVFV causing 400 deaths and TBEV causing 9,500 deaths. These estimates were based on a release of 50 kg of the virus, which at first may seem to be a substantial amount of virus; however, the capacity to produce Marburg virus was estimated at 250 tons and smallpox virus was 100 tons, so perhaps the 50 kg model for RVFV cited above is not as unrealistic as it initially seems. For comparison, a bacterial release of 50 kg of anthrax would disseminate far more than 20 km from the release line and infect 125,000 people with 95,000 deaths. With extensive use of bioreactors, the Soviet Union bioweapons program was able to produce anthrax in very large quantities. Compared with viruses, bacterial spores are environmentally very stable and can remain in the soil for more than 40 years.

Interestingly, a virus that caused an estimated 20–50 million deaths during an epidemic which started in 1918 was not weaponized. Although influenza virus was studied, it was not weaponized as part of the Soviet biological weapons program. This deadly virus causes countless naturally occurring cases where it infects and kills between 290,000 and 650,000 ([World Health Organization, 2020](#)) people and unknown numbers of animals each year. Although influenza virus may never have been developed as a bio-weapon, it did raise alarm when two teams of investigators conducted experiments which lead to much public debate and caused U.S. officials to impose a “pause” on some influenza research in 2014. The research of concern involved conducting studies for what is termed as “gain-of-function”. In these studies, virus characteristics, for example, change in the susceptible host range, could produce a more dangerous virus through the use of molecular biological methods ([Lipsitch and Ingelsby, 2019](#)).

Entomological Warfare

Since many important pathogens of humans are transmitted by arthropods, it is not surprising that biological weapons programs consider the use of arthropods as a means to deliver and spread certain pathogens. The Japanese successfully used infected fleas to deliver *Yersinia pestis* to cause plague in China ([Wikipedia, 2019](#)). Unsubstantiated reports have suggested that the U.S. considered the use of mosquitoes to deliver agents such as yellow fever virus. Interestingly, in 1939, a Japanese scientist tried to obtain YFV from the U.S. Rockefeller Institute Virology Laboratory presumably for inclusion in the Japanese Biological warfare program ([Regis, 1999](#)). The request was denied since resolutions by the League of Nations and a Congress of Tropical Medicine banned importation of the virus into Asia due to concerns that it might become established in the region. Accusations have also been made that in 1952 during the Korean War, the U.S. dispersed insects and spiders contaminated with anthrax and even rodents possibly infected with plague ([Regis, 1999](#)).

Agro-Warfare

From the above discussion, it is clear that for bio-warfare with humans as the target species, relatively few viruses have been considered since bacteria are more readily weaponized, stored, and delivered. Actual agricultural bio-warfare events have also predominantly focused on diseases caused by bacterial agents such as anthrax (*Bacillus anthracis*) and glanders (*Burkholderia mallei*). As mentioned above, glanders was first reported to be used by Germany to attack horses and mules that were a critical component of the transport and supply infrastructure on the battlefields of World War One ([Wheelis, 1998](#)). Nonetheless, when compared with agents targeted towards humans, those targeted towards livestock include a greater variety of viruses.

As demonstrated by numerous natural outbreaks, the economic impact of viral infections in livestock can be enormous. This is not only due to animal deaths, but also due to trade restrictions that can be imposed immediately upon detection of the pathogen and can last for years until a country is declared free of the pathogen. Viruses that are not zoonotic may be particularly attractive as bioweapons because they can be handled without the risk of the weapon developer becoming infected. Foot-and-mouth disease virus (FMDV) is perhaps the best example of a virus that has been weaponized for agro-warfare. This weaponization took place at the Russian Pokrov Biologics Plant, which is 50 miles east of Moscow ([Warrick, 2002](#)). The campus of this plant included five underground bunkers and had two FMD production lines that could produce 12 metric tons of the virus per production run.

A naturally occurring outbreak of FMD in the United Kingdom in 2001 is a good example of the devastation to agriculture that can be caused by a release of a virus in a new area. The U.K. FMD outbreak lasted for seven months and because at the time, vaccination was not allowed due to a European Union directive, the outbreak resulted in the slaughter of 6.6 million animals. The economic loss was estimated to have exceeded \$20 billion. A subsequent outbreak in 2007 had much less severe consequences lasting for four months with 2160 animals killed and the economic impact was \$200 million. Ironically, the 2007 outbreak was caused by virus released from the Pirbright laboratory site where a Government research facility and commercial vaccine research/production facility were located.

In addition to foot-and-mouth disease virus, there are other viruses that would be a threat to livestock including viruses in the families of: *Asfarviridae* (African swine fever virus) and *Paramyxoviridae* (rinderpest, New Castle disease virus).

The recent spread of African swine fever in Europe and China has caused much concern in agricultural communities. The virus has been introduced and eventually eradicated from several countries outside of Africa during the 20th Century, but in 2007 was identified in the country of Georgia. When it spread to Russia in 2012, Russia accused Georgia of swine fever sabotage, although there was no evidence to suggest an intentional introduction. Human activities, namely transportation of asymptomatic infected pigs and movement of infected feral pigs/wild boar, are potentially the cause of the spread of this virus over these large distances. The virus is now established in Armenia, Azerbaijan, Belarus, Czech Republic, Estonia, Georgia, Hungary, Latvia, Lithuania, Moldova, Poland, Romania, Russia, and Ukraine, and has recently been reported in Belgium. In August of 2018, the virus was reported in China and by March of 2019, infections had occurred in 28 provinces and nearly 1 M pigs were culled in efforts to control the virus. In addition to the devastation to the Chinese pork market due to culling of infected or exposed swine, an additional consequence of this outbreak is the unwillingness of customers to consume pork during the outbreak. This unconsumed pork could be the motivation behind one of the largest seizures of an agricultural product by U.S. customs. In 2019, U.S. Customs found 1 million pounds of smuggled pork from China (Hirtzer, 2019). An unintended consequence of unregulated trade in pork could be the introduction of a virus to a new area. Unfortunately, it is known that following the outbreak in China, there were other outbreaks occurring in Mongolia and South Korea. The question of intentional or naturally occurring outbreaks is not new; for example, an unexplained 1971 outbreak of African swine fever occurred in Cuba. This outbreak led to the slaughter of 500,000 pigs on the island and was blamed on the U.S. Central Intelligence Agency although the evidence to support the accusation has never been revealed (Chronicle, 1977).

Biological Agents for Good or Evil

The use of biological agents to control pests in the environment may be considered bioterrorism or a bio-crime by some people or as biological control by others. For example, in 1997, rabbit hemorrhagic disease virus was used by a small group of farmers to kill rabbits in New Zealand. For over 20 years, the lead perpetrator had been advocating with the New Zealand Agriculture Department for measures to control rabbits, which were causing millions of dollars of losses to farmers every year. Unsatisfied with the results of these discussions, the perpetrators illegally introduced the virus into several areas. This non-State sanctioned use of a virus could certainly be regarded as an act of agro-terrorism, albeit intended to control a wild introduced pest species (the European rabbit) with the purpose of reducing environmental damage, and the economic consequences to crop production and grazing for livestock. Since the 1997 release, the government has determined they should control the release of a variant of the rabbit hemorrhagic disease virus (RHDV1-K5) as a government sponsored project to control the rabbit population.

The use of viral hemorrhagic disease for rabbit control is very similar to the state sponsored use of myxoma virus, which causes myxomatosis, released in Australia on a large scale in 1950. This release is estimated to have reduced the rabbit population from 600 million to 100 million within just two years. The European rabbit, *Oryctolagus cuniculus*, that had been introduced into Australia by settlers, was regarded as a significant agricultural pest as early as 1887, when a £25,000 reward was offered to anyone that developed an effective control measure. The disease had first been reported in 1897 in a stock of European rabbits maintained at a hospital in Montevideo, Uruguay (Sanarelli, 1908). The potential use of the virus to control rabbits in Australia was proposed in 1927 (Aragao, 1927).

The success of the Australian release of myxoma virus probably inspired the release of the virus in France in 1952. Not unexpectedly, the virus quickly spread beyond the initial release site with devastating effects on the European rabbit population, not just in France, but subsequently in the Netherlands, Italy, Spain, and other European countries. Whilst people involved in agriculture were supportive of the effects of the release, hunters were outraged. In 1955, the person responsible for the initial release was prosecuted and fined 5,000 francs for his actions. Ironically in 1956, he was awarded a medal of achievement by the French Department of Rivers and Forests. This prosecution and reward for these actions indicate how controversial such releases of bioweapons or biological control agents are.

The first cases of myxomatosis in the U.K. appeared in the autumn of 1953 in the southern counties of Sussex and Kent. The virus spread rapidly and resulted in reductions in the rabbit populations similar to those experienced in Europe. Interestingly, the virus did not become established in New Zealand even though it was apparently introduced in the 1950s. An interesting aspect of myxomatosis in the U.K., is that it was tested on Gruinard Island where anthrax was also tested. Under the direction of Sir Charles Martin, rabbits on Skokholm Island were inoculated with the virulent strain B of the virus in 1936. Remarkably, there was no effect on the estimated 10,000 rabbit population, with similar failures experienced after follow-up releases in 1937 and 1938. The cause of this mysterious failure was not resolved until 1955. By this time, studies of the transmission cycle of Myxoma virus, had determined a key role of the rabbit flea *Spilopsyllus cuniculi* as a vector of the virus (Lockley, 1954). The rabbit population of Skokholm Island, was perhaps unique in that they were free of this ectoparasite (Lockley, 1955), demonstrating the importance of understanding everything possible about a biological agent in order to optimize its use against a target species. Although effective use of the virus to control rabbits was achieved in most places without this understanding, the knowledge would have been invaluable during the British plans to test the virus on an isolated population.

As a further point of interest, in Australia it was determined that a species of flea, *Echidrophaga myrmecobii*, which parasitizes marsupials, could transmit the virus; but importantly, a type of arthropod, namely mosquitoes, that are not a likely vector of the virus in its Native South America, could be an efficient mechanical vector. The role of mosquitoes as mechanical vectors in other countries does not seem to be well understood, but their role in Australia illustrates that one cannot assume that what is known

about a pathogen in the endemic region, will apply when introduced into a new area. Establishment of West Nile virus in the Americas since 1999, has also demonstrated this principle.

Clearly, these examples illustrate, how the perpetrator and intent can determine the subtleties of how an event is classified. What in some circumstances will define a release of an agent as legitimate and beneficial biological control, can in other circumstances be classified as terrorism, with consequences of fines and perhaps imprisonment.

Effects of Viral Introductions

Often the resultant effects from the natural spread of a virus can be used to model the potential effects of a bioterrorist attack using viruses. Three good examples are the effects from the introduction of West Nile to the Americas, porcine epidemic diarrhea, and highly pathogenic avian influenza viruses. West Nile virus (WNV) was introduced into the U.S. in 1999, although the route(s) of the initial introduction remains unknown, it is believed to not be a bioterrorism related event. Despite West Nile virus being a well-studied-virus with a record of frequent introductions from Africa into other countries, when the virus first came to the U.S. experts assumed that it was St. Louis encephalitis virus. This assumption was probably made because St. Louis encephalitis virus was a virus that occurred in the U.S. However, an astute veterinarian noticed the atypical fatal infections in birds and was insistent that St. Louis encephalitis virus was not the causative agent of the outbreak. In addition to revealing inadequacies of surveillance and initial reporting of a new viral introduction, this also showed inadequacies in the ability to predict viral spread following an introduction. Although initial predictions indicated the virus would be contained, it is now well documented that the virus continued to spread throughout the U.S. each year until it is now permanently established in the U.S., and in some other countries of the Americas, and continues to cause many severe illnesses and some fatalities in people, and in other species, notably horses. Although species of mosquito, for example in the *Culex pipiens* complex, that are principal vectors of WNV in endemic regions, are also present in the U.S., WNV has been detected in far more species in the U.S. than ever seen before. This demonstrates once again that one should be cautious in assuming that the characteristics of a pathogen in a new area will be the same as previously observed. Had the introduction of WNV been a deliberate bioterrorism attack, it would be regarded as a success. From probably a single introduction, its characteristics of being mosquito-borne, infectious to multiple species of vertebrates, and zoonotic with the ability to cause fatal infections, enable the virus not just to cause an outbreak but to become established permanently at a continental level and therefore continue to cause suffering and a financial burden. As a result of the introduction, there were costs to train people, conduct research, develop nationwide surveillance, and develop a blood screening capability and a veterinary vaccine. It is estimated that hospitalization and lost-productivity associated with each encephalitis WNV case can cost up to \$324,000, with a total cost for all hospitalized cases between 1999 and 2012 being \$778 M (Staples, 2014). One virus regarded as a potential bioterrorism agent, RVFV shares several characteristics with WNV. It is mosquito-borne, zoonotic, potentially fatal for humans, and dissemination would likely follow a very similar path as WNV, with the additional potential for large scale livestock losses.

In 2013, porcine epidemic diarrhea virus was introduced into the U.S., probably from imported animal feed products. The virus is now in 34 states and costs an estimated \$900 million to the swine industry with approximately 8 million pigs being culled. In 2015, an outbreak of highly pathogenic avian influenza resulted in the deaths of 50 million poultry with a total economic impact of \$3.3B to the U.S. (Blue Ribbon Study Panel on Biodefense, 2017).

Another viral disease of poultry, Newcastle disease (named because of a 1927 outbreak in Newcastle-upon-Tyne, U.K.), can infect over 250 different bird species with mortality ranging between 70 to 100%. A U.S. outbreak in 2002-03 began in backyard birds with cases in Arizona, Nevada, and Texas. Outbreaks in California commercial poultry industry lasted for 11 months, resulting in trade restrictions, with an estimated cost of over \$160 million, with 3.16 million birds being killed. Again, in California, outbreaks in commercial poultry operations were reported in December of 2018, and are ongoing at the time of writing.

Above, we have discussed threats to agriculture with a focus on pathogens of animals, including zoonotic viruses that also infect humans. In the context of agro-terrorism, plant targets could have an even more devastating impact on food security and the economy, albeit perhaps without the fear factor associated with potentially fatal human diseases. The USDA plant protection and quarantine's select agent and toxins list only includes bacterial and fungal agents. One of these, *Rathayibacter toxicus*, although a pathogen of ryegrass has the unusual property of producing a corynetoxin that at relatively low doses is lethal to vertebrates. Indeed, thousands of sheep and cattle die each year as a result of eating infected grasses. Parker listed banana bunchy top virus as a potential agricultural biowarfare or bioterrorism agent but Wheat dwarf geminivirus and Barley yellow dwarf virus were listed as having potential bioweapon applications (Parker, 2002). Other viruses of plants that could be threats include: Rice tungro virus, Wheat streak mosaic virus, Maize streak virus, Cassava mosaic virus, Tomato spotted wilt virus, Pepino mosaic virus, and the PVYNTN strain of Potato virus Y (Stack, 2019). The Russian biological weapons program supposedly weaponized Wheat stem rust and Rice blast and a fungus-based anti-crop bomb. Another example, is wheat blast which was supposedly developed and put in production by the U.S. in 1951 during the Korean War.

Conclusion

It is clear that there are many biological agents that have the potential to be used in a bioterrorism attack. Many of these agents are viruses that infect, humans, and/or economically important animals and plants that are part of important agricultural practices to provide food. Unlike chemical or radiological-based weapons, many biological agents can be relatively easily obtained at low

costs, since they occur in nature, often over wide geographical areas and relatively frequently. Simple internet searches provide real time information on where and when these agents are present. Having evolved to survive via various transmission cycles, viruses often have the capacity to spread quickly as demonstrated by large scale epidemics, and also, after introduction, to become permanently established in new geographic locations. Some of the viruses and bacteria can be infectious via aerosols, and some can survive for long periods of time, either in the environment or in asymptomatic but potentially infectious hosts. Although development as biological agents for bio-warfare purposes, necessitates large-scale production and processing capabilities, with regards to use for bioterrorism, preparation of an agent may be accomplished using relatively simple equipment and procedures. The availability of vaccines and treatments for several of the viruses of concern, or limitations of host range, for example with viruses that infect swine or plants but not people, working with these viruses could be accomplished by people without fear of infection. New technologies may provide the ability to genetically manipulate agents with increasing ease at low cost without specialist knowledge or equipment. For these reasons, biological agents may be considered as more practical and cost effective than chemical or radiological weapons. As such, we must be increasingly concerned and vigilant with regards to the use of biological agents to attack us or our agricultural systems upon which we depend. As their use becomes easier, we must assume that the probability of their use becomes greater.

The Use of Viral Promoters in Expression Vectors

Ian M Jones, University of Reading, Reading, United Kingdom and London School of Hygiene and Tropical Medicine, London, United Kingdom

An Introduction to Promoters

The origins of promoters and their manipulation are an integral part of the history of molecular biology. As DNA sequencing became commonplace following the development of the canonical Sanger and Maxam–Gilbert methodologies the possibility to align sequences and look for common elements arose. A number of sequences, often termed “boxes” in the original alignment studies, were identified upstream of the methionine encoding ATG marking the beginning of a translatable sequence. Such elements were found upstream of both bacterial and eukaryotic open reading frames although the sequences concerned were different. Combined with earlier molecular genetics studies which had defined *operators* (sequences that contained both promoter and repressor elements) it became apparent that such sequence elements were responsible for the control of gene expression. They include the promoter itself, often a control element and sequences around the start codon which serve to stabilize the transcript when it binds to the ribosome (Fig. 1).

Early molecular genetics experiments had shown, using gene fusions for example, that combining the promoter elements of one gene with the coding sequence of another led to a pattern of expression characteristic of the promoter, not the product and the first studies of heterologous gene expression, by the Boyer and Cohen labs, similarly demonstrated that combining bacterial promoters with eukaryotic coding sequences allowed eukaryotic protein expression in *E.coli*. These studies formally demonstrated the plug-and-play possibilities of expression vector design and many promoters were subsequently studied for use therein. Some of these, the *lac* promoter for example, are still used in expression vectors today.

Viral Promoters

The widespread use of viral promoters to control the expression of heterologous genes derives from the fundamental requirements of viruses to (1) initiate replication in multiple cell types and, (2) produce large amounts of the structural proteins necessary for virus assembly. This gives two classes of promoter, relatively *host independent* and *strong* respectively. Viruses typically exhibit tropisms, that is a preference for one cell or tissue type over another, a property that can be exploited when targeting particular cells by virus vectors, in gene delivery applications for example. Tropism can act at any stage of the replication cycle but the predominant restriction operates at the level of virus entry, the presence or not of the viral receptor on the host cell surface. Once

Fig. 1 A typical expression vector and promoter features. Left. All vectors will be usually equipped with a marker and origin of replication for growth in *E.coli*. They may, additionally, have sequences for particular uses, for example recombination sequences for integration into a virus vector or another form of carrier. One or more loci will be engineered to have cloning sites positioned at the optimum distance downstream of a defined promoter for transcription to initiate efficiently. A selectable marker and origin of replication for the target host may also be present. Right. A generalized promoter will bind RNA polymerase and initiate transcription at a defined nucleotide downstream. The 5' untranslated region is of variable length but sequences immediately 5' to the translation start may include Shine-Dalgarno (bacteria) or Kozak (eukaryotic) sequences that stabilize engagement with the ribosome. A transcription terminator will disengage RNA polymerase. Eukaryotic promoters may have an enhancer, necessary for high level or tissue dependent expression and are in consequence usually much larger than prokaryotic promoters. Canonical “boxes” of each are indicated.

Fig. 2 Viral promoter classes. Expression from viral promoters can result from infection by recombinant viruses or from transfection of DNA or RNA. The former is usually very efficient but may eventually kill the cells while the latter is usually less efficient but generally non-toxic. Once delivered promoters function as either early or late with the features indicated.

inside a cell it is in the best interests of the virus to initiate the replication cycle as soon as possible as failure to do so may result in the virus being degraded and the opportunity for infection lost. Accordingly, with some exceptions, early promoters, defined as those that are used immediately after virus entry are recognized by the host RNA polymerase and initiate RNA transcription without the need for particular co-factors. They are, in essence, universal “go” signals although they may be of limited strength as many early viral components are transcription factors or enzymes that are not needed in abundance. By contrast, late viral promoters are very strong transcription initiators dedicated to the production of copious amounts of message encoding the structural proteins needed late in the replication cycle to permit the assembly of progeny virions (Fig. 2). They require specific *trans* activators and often use a virally encoded polymerase making them much more restricted in terms of permissive cell type. This *early-weak cell independent, late-strong cell dependent* distinction occurs across the field of virology and is the fundamental property that has led to virus promoters being taken up as widely as they are, in viral expression systems themselves and as part of stand-alone expression vectors. There are exceptions, some RNA viruses may forgo the use of promoters, as is the case for some positive strand RNA viruses that translate their genome directly on virus entry, and negative sense and double stranded RNA viruses have promoters that are recognized only by the virus encoded polymerase. They have, nonetheless, been used for expression purposes within particular virus models and some have seen broad take-up in particular fields. The alphaviruses for example, which have a single strong internal promoter recognized by their own RNA polymerase, are in use today as part of the growing field of RNA vaccines although these uses are specialist cases and the promoters concerned are not in widespread use elsewhere.

Viral Promoter Examples

The use of virus promoters and viral systems in biotechnology applications is very widespread but some well-known examples serve to illustrate the general benefits of the early/late promoter choice. These include the use of the cytomegalovirus immediate early promoter in general eukaryotic expression vectors designed for transfection into mammalian cells, the use of the phage T7 late promoter in bacteria and the use of both early and late promoters in the baculovirus insect cell system.

Herpes viruses have gained popularity as vaccine vectors in recent years as they induce robust immunity at the sites where they establish latency, a positive aspect of the virus tropism noted earlier. Encouraging data have been obtained in macaque models for diseases such as HIV and TB that had previously responded only poorly to vectored vaccine approaches. In the recombinant herpes viruses used, up to 6 heterologous genes are expressed from a single virus backbone using, among others, the macaque cytomegalovirus immediate early (MCMV IE) promoter. As noted, immediate early promoters are those that are recognized by host RNA polymerase immediately on cell entry (IE genes are operationally defined as those which are active within the first 6 h of infection). The purpose of these vectors is to expose infected cells to the vaccine antigen in the early, inflammatory phase of virus expansion, leading to the induction of a robust immune response that is then boosted by the alternate cycles of latency and activation that are a herpes virus characteristic. But the CMV IE promoter is also used much more widely than within CMV based vaccine vectors. Along with the promoters of Simian Virus 40 (SV40) and Rous Sarcoma Virus, CMV IE1 was one of the earliest defined eukaryotic promoters and familiarity with its sequence, particularly the mapping of its boundaries, led to its widespread adoption in early plasmid expression vectors. In the virus genome CMV IE contains an active enhancer region several hundred bases upstream of the TATA box (cf. Fig. 1) which serves to bind several host transcription factors leading to the assembly of highly

competent transcription complexes and high levels of transcription. In a typical expression vector in use today, pcDNA3 for example, the enhancer-promoter sequences are found in a ~500 base pair fragment that is part of a selectable vector with other common features (cf. Fig. 2). Several of those features, the promoter for the neomycin resistance gene used for selection of eukaryotic cell transformants and the transcription termination signals are also derived from a virus, SV40, for the same underlying reasons already discussed. Further analysis of CMV IE has determined that the enhancer-promoter is modular and that the enhancer continues to function if appended to promoters from other genes, leading the construction of hybrid enhancer-promoters with even higher levels of transcription. In the pCAG vectors the CMV enhancer is abutted to the chicken actin promoter which also includes a non-translated exon and intron in addition to the promoter itself. Introns have been found empirically to improve the function of several eukaryotic expression vectors. They oblige the primary transcript to be processed by the splicing machinery which leads to a more stable message and higher levels of encoded product. These vectors also contain an origin of replication, again from SV40, that functions in eukaryotic cells expressing large T antigen, meaning that they replicate and pass to daughter cells at cell division so transfected cells are not diluted out in a growing culture.

An example of a virus late promoter in another expression host, *E. coli*, is provided by the T7 system developed over many years by Studier and colleagues. Its efficiency is such that it is the predominant bacterial expression technology in use today. Many additions to the system have been described including options to regulate the levels of expression and the use of particular *E. coli* strains to maximize productivity and the solubility of the translated product. But at its heart the system exploits the strong promoter found upstream of the late genes of bacteriophage T7. In keeping with the early/late divide already described, the T7 early genes are transcribed by *E. coli* RNA polymerase following the entry of the phage into the cell. A cascade of temporal gene expression results in replication of the T7 virus genome and a switch to late gene expression. This is achieved by synthesis of a dedicated RNA polymerase which is not only more processive than *E. coli* RNA polymerase but is also specific for T7 late promoters which are unique and do not share the common promoter elements described in Fig. 1. As a result, anything cloned downstream of a T7 promoter in a plasmid vector is transcribed selectively and abundantly when T7 RNA polymerase is present. If that vector is also multicopy a gene dosage effect also comes into play and very high levels of synthesis are possible. Today's systems match engineered *E. coli* strains, which have the gene for T7 RNA polymerase integrated into the chromosome under control of a *lac* promoter, with a variety of vectors with the T7 promoter. Induction of expression is indirect with activation of the *lac* promoter by IPTG, or manipulation of the growth medium, to induce expression of the T7 polymerase which, in turn, transcribes a vector resident target gene. The specificity of the T7 polymerase for the T7 promoter is a restriction when gene expression from other promoters is required and other bacterial virus promoters, recognized by *E. coli* RNA polymerase are also used, from phages lambda and phage T5 for example. But the strong-late features of the T7 system have made it a default for bacterial expression experiments and variations of it have also been developed for eukaryotic cells although they are not in widespread use. The specificity of polymerase and promoter has also allowed the development of transcription vectors and systems designed for the production of RNA *in vitro*. Phage T7 and the closely related phages T3 and SP6 are all used for these systems as they all share related late promoters that are transcribed efficiently by their cognate RNA polymerases.

A system that has made use of both early and late viral promoters is the baculovirus insect cell system. Its earliest descriptions for heterologous gene expression, and its origins as an expression system, described the use of the very late polyhedrin promoter to transcribe an inserted gene. Polyhedra are crystalline arrays of a single viral protein which trap virus particles to afford them a high degree of environmental protection, from desiccation or UV irradiation, for example, both inherent risks for virus transmission on plant surfaces. Two features follow from this description, very late promoter function is uncommonly strong, to generate the amount of polyhedrin protein required to coat multiple virus particles, and its need for survival in the environment means that it plays no role in tissue culture. Accordingly, the gene encoding polyhedrin can be replaced with a gene of interest so that, late in infection, very high levels of RNA encoding the heterologous protein are produced (Fig. 3). The polyhedrin promoter, and several others similarly classified as very late, conform to the dependency previously noted as their transcription is achieved with a virus encoded RNA polymerase, a eukaryotic equivalent of the T7 system, and so function is restricted to virus infected cells. Despite its strength, the polyhedrin promoter is transcriptionally silent in the absence of virus infection so its general use, as described for CMV IE for example, is not possible. In some recombinant virus systems, the exchange of a viral for recombinant gene results in an attenuated phenotype that requires a *helper* virus or cell line to be overcome. But in recombinant baculoviruses this is not the case and recombinant viruses grow to the same titer as unmodified viruses, facilitating large scale expression, including at industrial scale. As replication is not impaired a gene dosage effect also applies, a further parallel with the T7 system. Variations in the system since its inception in the early 1980s have provided toolboxes for high level expression of single and multiple genes as well as the means to generate the recombinant viruses easily. In fact, the use of early promoters was also investigated, based on the idea that, productive as it is, polyhedrin promoter driven expression occurs at the end of the replication cycle and so recombinant protein expression is limited by the fact the cell is dying (baculovirus infections are lytic). An early promoter driven heterologous gene might allow expression throughout the replication cycle and so accumulate to higher levels overall. This turns out not to be true but the study of early promoters has given rise to a transfection based system for insect cells that mirrors the transfection of mammalian cells with the CMV IE based vectors already described. IE promoters in baculoviruses, including in the default virus used, *Autographa californica* multiple nuclear polyhedrosis virus (AcMNPV), are low strength, the default early-weak situation already encountered. However, when combined with homologous regions found in the baculovirus genome, *hrr* sequences, transcription from them improves dramatically. In effect *hrr*s act like the CMV enhancer already described although they do not bind transcription factors but rather act as origins of replication or chromatin opening sequences. Subsequent improvements have systematically optimized the sequence of each component of such IE promoter based transient expression vectors so that their

Fig. 3 The baculovirus expression system in which both early and late viral promoter choices are available. The most exploited virus used is *Autographa californica* multiple nuclear polyhedrosis virus. In the canonical system the very late polyhedrin gene is exchanged for a genetic cargo by integration *via* sequences homologous to the flanking genes encoding ORFs 603 and 1629. The approximate extent of sequence used in common vectors is indicated by the red lines. In early promoter vectors, an early promoter such as IE1 is combined with a h sequence, usually hr5, to enable transcription directly upon transfection. In more recently optimized vectors both early and late promoters are present with cloning downstream of both allowing either to operate. Transfection of insect cells results in direct protein expression from either IE1 or IE2 which can be boosted by superinfection by AcMNPV itself which provides the *trans* acting factors to allow p10 to function. True recombinant virus formation can occur *via* the same technology as the canonical example. Irrespective of promoter use the default site of integration is the polyhedrin locus although other sites in the genome have been used. Bent arrows – promoters. Bent blocks – terminators.

productivity following insect cell transfection rivals many mammalian transient expression systems (Fig. 3). The vectors also contain sequences that allow recombination into the baculovirus genome meaning that screening can be performed by transient expression and the most promising construct can be used directly to generate a recombinant virus suitable for scale up.

These three examples, which vary promoter use and the phyla in which they operate, demonstrate the properties of viral promoters that have led to them being so exploited. Indeed, triple viral promoter vectors, comprising the T7 promoter, part of the CMV promoter and a baculovirus promoter are in common use, allowing a screening of expression in various hosts with one plasmid construct.

Further Viral Promoter Use

Viral promoters also feature in less generally used expression systems such as the growing area of expression *in planta*. The attractions of expression in plants are obvious, huge production and lack of adventitious agents, and they remain attractive today even if the vision of edible pharmaceuticals, the “*vaccine in a banana*” has faded somewhat. Virus vectors are an integral part of these developments and a plant virus promoter, the 35S promoter from Cauliflower Mosaic Virus (CaMV), dominates the expression field. 35S is one of two promoters found in the virus and is both strong and relatively cell type independent. Unlike the very late promoters of baculoviruses the 35S promoter is not used as part of recombinant virus system, the plant cell wall limiting how easily virus infections can be performed. Instead 35S is used alone, in various optimized sequence forms, as part of a genetic construct that is delivered to the plant by the invasive bacterium *Agrobacterium tumefaciens* which transfers a section of its DNA, T-DNA, which itself can be modified to carry other sequence, into the plant cell. The combination of plant cell delivery by *Agrobacterium* with the use of the 35S promoter was the predominant methodology of the rapid expansion in transgenic crop experiments from the mid 1980s onwards until this research area was curtailed by concerns over the release of genetically modified organisms. The almost unparalleled performance of the 35S promoter however has continued in the more recent transient plant expression technologies which, effectively, mass transfect plants with vectors for a limited period before harvesting the expressed product. These vectors are based on several types of plant viruses but are used predominantly in a *deconstructed* form in which plasmid based subgenomic versions of the virus genome are used to derive the nucleic acid that will ultimately be delivered into the plant cell (Fig. 4). One example among many is the use of vectors derived from Cowpea Mosaic Virus (CPMV) which have had their non-translated sequences, the sequences which flank the inserted gene, optimized for transcription and translation rather than replication. Such vectors do not replicate, so efficient delivery *via Agrobacterium* is essential, and at scale this is done by vacuum infiltration of the entire plant rather than localized syringe based delivery to individual leaves, but the core expression cassette remains an optimized CaMV 35S promoter flanked by the optimized CPMV sequences (Fig. 4).

A last example of the disparate use of viral promoters is in the field of RNA vaccines, thrown into focus recently by the need to rapidly develop and deploy vaccines for Covid-19. The benefits of an RNA only approach to a vaccine can be found elsewhere but the technology concerned falls into one or other of two types, direct translation of a vaccine candidate antigen by

Fig. 4 Viral promoter use in typical plant expression technologies. Left. Transgenic plants are selected following delivery of a vector to plant cells. The Cauliflower mosaic virus 35S promoter is used for expression of both the selectable marker, such as hygromycin resistance, and the transgene. The entire plant is regenerated from the transformed tissue and may be fertile, leading to widespread propagation. Right. Transient plant expression makes use of the RNA2 of Cowpea mosaic virus which normally produces the virus structural proteins. The 35S promoter is used to transcribe the RNA which, as a result of the optimization of the remaining RNA2 sequences is abundantly translated, even in the absence of replication. The system is destructive and cannot be propagated. Bent arrows – promoters. Bent blocks – terminators.

Fig. 5 Viral promoter use in RNA vaccines. Left. Technologies which mimic messenger RNA use efficient *in vitro* transcription with T7 promoter and polymerase to produce copious amounts of a synthetic RNA with optimized 5' and 3' UTRs. The message mimic is achieved by using a cap analog to initiate transcription and including a polyA tail which can be added co- or post-transcription. The transcript may also include modified bases to minimize degradation. The amount of vaccine antigen is directly related to the amount of RNA delivered. Right. Technologies that use self-amplifying RNA make use of the natural replication cycle of alphaviruses but substitute the structural genes for a candidate vaccine. Vaccine antigen is not immediately produced on vector delivery. Rather RNA replication occurs to reveal the SPG promoter on the negative strand and further transcription from it produces the sgRNA messages that encode the vaccine antigen. The system is multiplicative with many more copies of the message produced than numbers of the original RNAs delivered. Bent arrows - promoters.

a synthetic messenger RNA delivered to cells by transfection or a self-replicating RNA which, as a consequence of its design, also produces a translatable message. Both technologies use strong viral promoters, the former for the enzymatic synthesis of the RNA *in vitro* that is to be used, using the phage polymerases discussed for T7 and its relatives, and the latter a specific viral promoter active following RNA replication. The advantage of the self-replicating technology is that lower amounts of RNA need to be delivered to cells to produce the same therapeutic outcome. The self-replicating facility, and the promoter used to drive expression of the vaccine antigen, exploit the alphaviruses noted briefly at the beginning of this article. Alphaviruses have message-like positive sense RNA as their genome but only translate two thirds of it on virus entry into the cell. This produces the viral replicase which sets about replicating the genome to produce a complete negative sense copy of the genome. The negative sense RNA acts as template for more positive sense RNAs including, at this stage, large amounts of a subgenomic RNA (sgRNA) which arises from an internal promoter (SGP) only active in the negative sense strand. In the virus the sgRNA encodes the structural proteins and the use of the incoming template or the later sgRNA effectively mimics the early/late switch of promoter already described for viruses generally. If the virus structural proteins are replaced by sequence encoding a candidate vaccine antigen the hybrid provides a self-amplifying RNA system in which a single incoming transcript generates multiple messages encoding the vaccine antigen and the process continues whilst the replicase remains functional (Fig. 5). Like the polyhedrin or T7 examples the use of SGP is virus specific as it is recognized only by the alphavirus replicase, it has no value for use in generalized expression vectors.

Viruses are the chancers of the natural world and their ability to try and replicate in any cell they encounter underpins their pathology and zoonotic potential. Natural barriers to infection prevent this occurring on a wide scale, from the selective use of receptors, through induction of immunity to specific requirements for virus assembly and release. However, for many viruses bypassing these blocks, by delivery of virus nucleic acid directly into cells, has demonstrated their ability to complete at least part of their replication cycle in many cell types. This ability derives from early viral promoters being able to function in many cellular environments and, if the required *trans* acting factors are present, the ability of the late promoters to drive synthesis of the virus structural proteins. This mix of promoter types, fundamental to virus biology, has been widely exploited in the expression vectors in use today. Understanding virus promoter function, defining the sequences required and their boundaries, has allowed their optimization and, increasingly, their combination with control elements has permitted their development as part of very finely tuned and productive expression applications. A promoter promotes, and in the case of viral promoters that promotion has been of an innovative field of biotechnology as much as of the transcript itself.

Nomenclature

Ad	Adenovirus	ICI	Immune checkpoint inhibitors
ANTXR1	Anthrax toxin receptor 1	ICP	Infected cell protein
ATP	Adenosine triphosphate	IFN	Interferon
CD	Cluster of differentiation	OV	Oncolytic virus
CRT	Calreticulin	PAMP	Pathogen-associated molecular pattern
CTLA4	Cytotoxic T-lymphocyte-associated protein 4	PD-1	Programmed death receptor 1
DAF	Decay-accelerating factor	PD-L1	Programmed death receptor ligand 1
DAMPs	Danger associated molecular patterns	RB	Retinoblastoma
GM-CSF	Granulocyte-macrophage colony stimulating factor	TAA	Tumor-associated antigens
HMGB1	High-mobility group protein box 1	TEM8	Tumor endothelial marker 8
HSV	Herpes simplex virus	TIM3	T cell immunoglobulin and mucin domain 3
ICAM1	Intercellular adhesion molecule 1	TK	Thymidine kinase
ICD	Immunogenic cell death	T-VEC	Talimogene Laherparepvec
		VEGF	Vascular endothelial growth factor
		VSV	Vesicular stomatitis virus

Glossary

Cancer vaccine	A method of treatment that boosts the immune system to fight cancer cells.	Immunotherapy	A method to treat cancer using components of the immune system.
Cold/hot tumor	Tumors that do not allow infiltration of T-cells are characterized by a cold environment; on the contrary tumors infiltrated by immune cells are displaying a hot environment.	Oncolytic virus	A virus that preferentially infects and kills cancer cells.
Combination therapy	A method of treatment that combines two or more therapeutic agents.	Pattern-recognition receptors	Cellular receptors specialized in recognizing antigens found in pathogens; they have an essential role in innate immunity.
Immune checkpoint inhibitors	Therapeutics that block immune checkpoint pathways.	Targeted therapy	A method of treatment that identifies and attacks a certain type of cell.
Immunogenic cell death	A type of cell death that triggers an immune response.	Tumor-associated antigen	Antigens preferentially expressed in tumor cells.

Introduction

Oncolytic viruses (OVs) are replication competent viruses that infect and destroy cancer cells without harming adjacent normal tissue. Evidence for the use of viruses for cancer treatment can be traced to more than a century ago. Several case reports of leukemia and lymphoma patients described signs of transient disease regression following viral infections such as influenza, measles, chicken pox, hepatitis and glandular fever, while a 1910 report presented a case of cervical cancer regression after immunization with the live attenuated rabies vaccine. In the second half of the 20th century, major advances in electron microscopy and tissue culture techniques accelerated the understanding and scientific investigation of viruses. The first clinical trial of an OV started in 1949 to assess the effect of hepatitis B virus in a cohort of 22 patients with Hodgkin's disease. Several patients had a positive response to treatment. However, more than half developed hepatitis resulting in several deaths, highlighting the importance of thorough preclinical investigations. The introduction of animal cancer models offered this opportunity and many other naturally occurring human and animal pathogens were evaluated for their anti-cancer potential such as Egypt 101 virus, Coxsackievirus, adenoidal-pharyngeal-conjunctival virus, and mumps virus. Although full of enthusiasm, the early era of oncolytic virotherapy research and clinical studies was also riddled with unethical practices and was followed by a decrease in scientific interest in the 1980s and 1990s.

In the 1990s, major advances in molecular biology opened the possibility to engineer OVs with increased tumor specificity and reduced pathogenicity. The first OV to be adapted for targeted cancer therapy was herpes simplex-1 (HSV-1). Mutations in the gene encoding for thymidine kinase rendered the virus incapable to propagate in non-dividing cells, thus limiting virus replication to actively dividing tumor cells. Extensive investigations of numerous OV platforms culminated with the first clinical approval of adenovirus-derived Oncorine for the treatment of head and neck cancers in China in 2005, and the first global clinical approval of the modified HSV-1 Talimogene Laherparepvec (T-VEC) for the treatment of unresectable melanoma in 2015. These major

milestones are complemented by the numerous clinical trials of OV currently underway that have resulted from steady scientific progress in oncolytic virotherapy over the last decades.

Modes of Action

OVs employ several mechanisms to infect and destroy cancer cells. In a direct mechanism, OV specifically infect and replicate in tumor cells and the tumor-associated microenvironment, leading to oncolysis and the release of new virus particles that continue to infect neighboring malignant cells. Additionally, viral particles entering the circulatory system can travel, to detect, infect and destroy remote tumors. However, the major mode of action for OV is the induction of immunogenic cell death (ICD) and the stimulation of a cytotoxic immune response against tumor antigens. Tumor growth is conditioned on escaping the surveillance of the immune system. This local immunosuppression is termed a “cold tumor”. OV-induced ICD engages different cell death pathways to infiltrate the tumor with immune cells and convert the “cold tumor” into a “hot tumor” and primes the immune system against cancer cells. Viruses employ numerous methods of ICD: apoptosis, necrosis, necroptosis, pyroptosis, and autophagic cell death, with each OV inducing a predominant form of cell death. ICD causes the release of tumor-associated antigens (TAAs) and danger-associated molecular patterns (DAMPs) such as surface-expressed calreticulin (ecto-CRT), nuclear high mobility group box 1 (HMGB1), ATP, and the production of type I interferons (IFNs). TAAs and DAMPs are recognized by innate effector cells such as dendritic cells and macrophages that activate tumor-specific T cells to establish adaptive immunity. For example, studies of melanoma patients treated with T-VEC have shown an increase of CD8⁺ and CD4⁺ T cells that was positively correlated with the outcome of treatment.

PVSRIP0 is a chimera OV of polio and rhinovirus that showed efficacy in a phase I clinical trial against recurrent glioblastoma, currently under further investigation in a phase II clinical trial. PVSRIP0 has been shown to promote IFN-dominant activation of dendritic cells and tumor-specific cytotoxic T cells in a range of solid tumors *in vitro*, and in an animal model of melanoma. Treatment of melanoma patients with CAVATAK (Coxsackievirus A21) showed an increase of CD8⁺ T cell infiltrates within the tumor microenvironment and up-regulation of immune-related response genes. In addition, several OVs have shown a potent tumor-associated anti-angiogenic effect. However, the process of cell infection by OVs also causes the release of pathogen-associated molecular patterns (PAMPs) that bind to pattern-recognition receptors (PRRs) and trigger the innate and adaptive anti-viral host immune response. Therefore, the success of oncolytic virotherapy is conferred by a balance between the viral escape mechanisms and the anti-viral and anti-tumor immune response.

Tumor Targeting by OVs

Tumor targeting is a complex process that takes advantage of differences between cancer and normal cells and the genetic features of OVs. Numerous OVs use specific receptors to infect tumors which are often overexpressed or restricted to cancer cells. For example, poliovirus employs cluster of differentiation 155 (CD155) as the cellular gateway; Coxsackievirus A21 targets cells expressing the intercellular adhesion molecule-1 (ICAM-1) and the decay-accelerating factor (DAF); anthrax toxin receptor I (ANTXR1), also known as tumor endothelial marker 8 (TEM8) is the high affinity cellular receptor for oncolytic Seneca Valley Virus; and laminin is the cellular mediator for Sindbis virus cellular entry.

The transformation of a cell upon virus infection (i.e. “the hallmarks of virus infection”) shares many similarities with the malignant transformation of cells (known as the “hallmarks of cancer”). These changes contribute to the preferential targeting of tumors associated with many viruses and can be employed to design highly selective virus vectors that complement the phenotype of cancer cells. Some OVs such as Seneca Valley virus, Newcastle disease virus, reovirus and vesicular stomatitis virus have a natural tropism for certain types of tumors. On the other hand, many OVs are genetically engineered to target and destroy tumor cells, and to reduce their toxicity to the non-transformed tissue.

A common feature for cancer cells is a defective interferon pathway employed to escape immune surveillance and apoptosis. At the same time, the loss of interferon defense renders cancer cells more susceptible to virus infection. For example, pelareorep, a wild-type variant of reovirus, is a weak pathogen common to humans that displays oncolytic properties in a variety of cancer types exhibiting activated Ras signaling and a deficient interferon pathway. Recombinant OVs also capitalize on the deficient interferon defense of cancer cells. Vesicular stomatitis virus (VSV) has natural selectivity for IFN-deficient transformed cells. Interestingly, the addition of a human IFN- β gene preserved the cancer cell toxicity of VSV, and decreased toxicity and enhanced the human IFN β -mediated anti-viral activity of neighboring non-transformed cells. VSV-hIFN β is currently under clinical investigations (see “Relevant Websites section”).

The removal of infected cell protein (ICP) 34.5 has eliminated the neurotoxicity of HSV and rendered the virus sensitive to the interferon response in non-transformed cells, thus limiting the virus replication to cancer cells. Clinically approved T-VEC has improved on this platform through additional modifications: the deletion of viral ICP47 and the addition of two copies of human granulocyte-macrophage colony stimulating factor (GM-CSF). Deletion of ICP47 enhanced intra-tumoral virus replication which translated into an increase of tumor cytotoxicity and strengthened the anti-tumor immune response. The addition of GM-CSF transgene is the most utilized modification in the development of recombinant OVs. Local release of GM-CSF promotes dendritic cell maturation that stimulates the anti-tumor immune response by increasing systemic and local CD8⁺ T cells.

Other OV platforms used the deregulation of the cell cycle as a targeted strategy for cancer therapy. Thymidine kinase (TK) is a cell-cycle dependent enzyme and a tumor marker. Deletion of TK in the viral genome causes virus dependence on the cancer cells' high-thymidine nucleotide pool for replication. First reported in 1991, TK deletion is the basis for the tumor targeting ability of the engineered Vaccinia virus. Two modified strains are currently in phase II/III clinical trials for different types of cancer. Other modifications include the addition of GM-CSF in the JX594 strain and the removal of both copies of vaccinia growth factor in Pexa-Vec.

Human adenovirus (Ad) is one of the most investigated oncolytic platforms due to its efficacy and ease of genome manipulation. However, the wild type Ad strains are not specific to cancer cells and display a high immunogenic profile, raising questions about the safety and efficacy of their use. Therefore, oncolytic Ads must be modified for therapeutic use. The first genetic modification of an adenovirus strain removed the E1B-55k protein and was aimed to target p53-deficient cancer cells. E1B-55k is an inhibitor of p53-dependent apoptosis. It was postulated that in normal cells in the absence of E1B-55k, virus infection would trigger p53-dependent cell death and limit virus replication. Therefore, a successful virus infection and replication is limited to inactivated p53 tumor cells. However, in addition to p53 inactivation, E1B-55k mediates late viral RNA export which subsequently was shown to be the trigger for selective amplification of virus in cancer cells. Nevertheless, the rationale for the virus construct design is still valid. Further deletion of E3B gene in a hybrid Ad2/Ad5 virus was designed to escape viral immune surveillance and was tested in clinical trials under the trade name ONYX-015 (Onyx Pharmaceuticals, California, USA) as single therapy or in combination with chemotherapeutics. Onyx-015 was the basis for the very similar virus construct H101 which became the first oncolytic virus to be clinically approved for the treatment of head and neck cancer in China under the tradename Oncorine (Shanghai Sunway Biotech, Shanghai, China). The next generation of modified Ad is represented by the Delta-24-RGD prototype. Based on Ad5, this mutant capitalizes on the array of viral genes that target cell cycle regulators, including the retinoblastoma (Rb) tumor suppressor pathway. Adenovirus replication is dependent on the release of transcription factor E2F from the Rb-E2F complex. A 24-nucleotide deletion in the Rb-binding domain of E1A gene leads to a defective viral protein that is incapable of binding Rb protein and releasing E2F. This limits viral replication to cancer cells where the absence of Rb protein renders E2F free. Further, the insertion of an RGD (Arg-Gly-Asp) peptide in the viral fiber knob increased tumor cell specificity by targeting integrins often expressed in cancers.

A different approach to select for highly efficient oncolytic virus particles that can escape immune surveillance by bioselection or "directed evolution". This strategy was used for the development of enadenotucirev, also known as ColoAd1. Enadenotucirev is a hybrid Ad3/Ad11p generated by serial passaging in colon cancer cells under stringent conditions of a pool of different serotypes of adenovirus. The chimeric virus proved highly efficient in killing epithelial-derived cancer cells and its safety and efficacy profiles have been investigated in a range of clinical trials. Taking it a step further, enadenotucirev was engineered as a drug delivery platform. The viral platform was shown to support the expression of full anti-VEGF antibodies in tumors, without compromising its replication and oncolytic function.

The ability of OVs to stimulate an immune response against tumor cells is exploited in the quest for developing cancer vaccines. As well as the insertion of GM-CSF, arming OVs with immunogenic transgenes such as cytokines, immune checkpoint inhibitors or co-stimulatory molecules was shown to enhance tumor specific immunity in mouse models and human clinical studies.

Combination Therapies

Human tumors are notoriously complex. Understanding the mechanism of virus oncolysis and cancer biology are essential in devising therapeutic strategies, which often include a combination of therapeutic platforms. Numerous studies of oncolytic viruses have shown synergy in combination with standard cancer treatment procedures such as radiotherapy and chemotherapy. Recently, the development of cancer immunotherapy and the emergence of immune checkpoint inhibitors (ICI) have changed the cancer treatment paradigm. Immune checkpoints are molecular pathways that regulate the response of immune cells essential to recognize normal tissue and to promote self-tolerance. Tumor cells have evolved to manipulate these pathways and become invisible to the immune defense by triggering inhibitory signals through the interaction of tumor cell-expressed receptors and their T cell-expressed ligands. For example, the tumor cell programmed death receptor ligand-1 (PD-L1) binds the programmed death receptor 1 (PD-1) on regulatory T-cells; high-mobility group protein box1 (HMGB-1) binds to T cell immunoglobulin and mucin domain 3 (TIM-3); and B7 binds to the cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) expressed in activated T-cells, triggering inhibitory immune response signals against tumor cells. Immune checkpoint inhibitors are antibodies and small molecule chemicals that work to boost the body's immune response to tumor cells. Several ICIs have been tested as monotherapy. Nevertheless, the activity of ICI is enhanced in combination with OVs due to their complementary mode of action. Thus, OVs create a hot tumor environment that has higher immunogenicity, which is a favorable factor for a successful immunotherapy. Indeed, numerous preclinical and clinical trials of combination therapy of OVs and checkpoint inhibitors show promising results. Taking it a step further, arming oncolytic viruses with ICI was also attained. The Western Reserve Vaccinia virus strain modified by inserting anti-PD-1 antibodies was as successful in controlling tumor growth in a mouse model of fibrosarcoma as the two agents administered in combination, and superior to each agent alone.

Conclusion

The development of novel oncolytic virotherapy platforms is an exciting paradigm in the search of innovative cancer therapies. OVs function as self-amplifying drugs with the ability to specifically infect certain cells, making them highly attractive candidates

for the development of targeted cancer therapies. In addition, the possibility to engineer viruses to increase their specificity, reduce toxicity to healthy tissue, and arm them to deliver anti-cancer treatments to tumors, makes them a very versatile tool. There are numerous clinical studies underway that investigate the efficacy of oncolytic viruses either alone or in combination with other therapeutic platforms. The results of these studies will offer more insight into the optimum conditions for treatment, duration and side effects, and will lead to new clinical options for targeted cancer therapy that improve outcomes for patients.

Introduction to Virus-Like Particles

Virus-like particles (VLPs) are protein complexes that are similar to, or even indistinguishable from, native virus particles, but that do not contain the viral genome. Hence, they cannot replicate but can mimic the viral antigenicity without being pathogenic. Depending on the biology of the virus, VLPs can be icosahedral or helical (rod-shaped), consist of one or more capsid proteins in multiple copies and may be enveloped or not. While VLPs can occur naturally (e.g., poliovirus empty capsids outside of the cell), they can also be recombinantly produced by expressing the proteins required for VLP production. While some VLPs self-assemble from a single type of coat protein (e.g., L1 of human papillomavirus), other VLPs require the presence of multiple structural proteins (e.g., bluetongue virus VLPs), or a combination of structural and non-structural proteins (e.g., poliovirus VLPs).

Their repetitive surface structure and size of 20–200 nm make VLPs highly immunogenic. They are capable of inducing a strong humoral and cellular immune response and are therefore attractive vaccine candidates for use in humans and other animals. Furthermore, a range of different VLPs have been shown to efficiently present foreign antigens on their surface and/or be loaded with substances of interest, such as, for example, nucleic acids, small peptides and other pharmaceutical substances. These properties make the use of VLPs an attractive approach for the development of new vaccines and as nano carriers for therapy of cancer and chronic diseases (Fig. 1).

Compared to other vaccination strategies, VLPs have advantages regarding safety and efficacy: they are safer than inactivated and live-attenuated viruses, because they cannot replicate and do not require the cultivation of live viruses. Hence, there is no risk of adverse mutations and accidental release of pathogenic viruses to the environment. This, coupled with their size and repetitive structure, makes VLPs ideal vaccine candidates compared to subunit and DNA vaccines.

As VLPs are empty shells, they can be less stable than the native virus in cases where the viral nucleic acid contributes to particle stability. This can cause problems for their production, storage and antigenicity. However, in some cases, for example poliovirus VLPs, the empty capsids can be stabilized by the incorporation of stabilizing mutations within the capsid proteins. Another strategy to improve VLP stability is the production of pseudo-virions, containing non-infectious nucleic acid. This was shown to be effective for HPV VLPs where the co-expression of L1 and L2 of human papillomavirus (HPV) and a circular dsDNA replicon in plants led to the integration of circular DNA into the VLPs and improved their stability compared to empty particles.

Another possible disadvantage with VLPs can be low yield, which makes the production of some VLPs cost intensive. Furthermore, necessary post-translational modifications, for example glycosylation, must be considered during VLP design to achieve the greatest similarity between VLPs and native viruses. These issues can be addressed by choosing a suitable expression system.

Immunological Properties of Virus-Like Particles

VLPs are able to induce both a humoral and cellular immune response as shown in Fig. 2. The high efficiency of VLPs is mainly based on their size, in the range of about 20–200 nm, their highly organized repetitive surface structure and their ability to stimulate toll-like receptors (TLRs). These features are also exploited when VLPs are used to display foreign antigens, unrelated to the VLP itself, and to deliver other pharmaceuticals, for example in cancer therapy or treatment of chronic diseases.

VLPs and the Induction of the Cellular Immune Response

To induce a cellular immune response and activation of cytotoxic T-cells (CTLs) and CD4⁺ T helper cells, antigens must be efficiently taken up by antigen-presenting cells (APC), such as dendritic cells (DC) or macrophages. The efficiency of antigen uptake into APCs depends on size, shape, receptor interactions and surface properties (charge, hydrophobicity, hydrophilicity) of the antigen. Here VLPs are superior compared to larger particles or complex formations over 200 nm. The size of VLPs allows them to freely drain and enter the lymphatic system and lymph nodes without the need for being transported by skin-resident DCs, enabling a fast and efficient uptake of antigen in conventional DCs and lymph node-localized DC subsets such as CD8⁺ lymphoid DCs and plasmacytoid DCs. In addition to the benefits of their size, the shape and surface properties of VLPs are advantageous compared to soluble subunit vaccines. VLPs consist of one or a few proteins in a highly repetitive and organized structure, which differs from almost all macromolecular structures in the host and can be easily detected as foreign by the immune system. Natural IgM antibodies efficiently bind to these surfaces, resulting in activation and recruitment of different complement components, such as mannan-binding protein (C1q) or pentraxin, which facilitates and promotes the trapping of particles in the lymphoid organs and uptake by APCs. Following uptake by APCs, the VLPs are degraded into peptides and can be presented on MHC class I and MHC class II molecules. MHC-class I presentation leads to the priming of CD8⁺ cells, which then mature into memory cytotoxic T cells (CTLs) or effector CTLs. Effector CTLs secrete different cytotoxins, such as perforin and granzymes, which lead to apoptosis of the target cell. MHC-class II molecules activate CD4⁺ cells resulting in the release of T-cell cytokines, which are essential for B-cell antibody class-switching and activation and growth of effector CTLs.

Fig. 1 Biotechnology uses of VLPs: Particles for use directly as vaccines can be produced by expressing the required viral proteins for VLP assembly. These VLPs mimic the antigenic properties of the native virus but do not contain the viral genome. In other approaches, VLPs can be conjugated with one or more antigens and/or loaded with nucleic acid, peptides or other pharmaceutical substances of interest.

Fig. 2 General induction of humoral and cellular immune response by VLPs: the particles are taken up by antigen-presenting cells, e.g., dendritic cells (DCs) or cross-bind to B-cell receptors (BCR). Antigen processing in DCs leads to presentation of the antigen on MHC-I or MHC-II molecules which leads to the recruitment and activation of $CD8^{+}$ and $CD4^{+}$ cells by binding of the presented antigen to the T-cell receptor (TCR). $CD8^{+}$ cells differentiate into memory and effector CTLs which recognize infected cells and secrete cytotoxins which cause apoptosis of the target cell. $CD4^{+}$ cells differentiate into $CD4^{+}$ helper cells which secrete cytokines, which leads to B-cell antibody class switching and activation and growth of effector CTLs. Activated B cells differentiate into antigen specific plasma cells, which secrete the respective antibody, and antigen-specific memory B cells, the premise for long term immunity.

VLPs and the Induction of the Humoral Immune Response

As described for the cellular immune response, the ability of VLPs to directly enter the lymph nodes has a significant impact on the humoral immune response. By reaching the lymph nodes in the native state, antigens can directly interact with follicular B cells. This is important to directly expose antigens to the B-cells and to develop an antigen depot in the germinal center which maintains B cell activation for several weeks after vaccination. Furthermore, the structure of VLPs enables cross-linking of B cell receptors (BCRs) which is a strong signal for B-cell activation, even in the absence of T-helper cells. The repetitive nature of VLP surfaces activates complement-facilitating B-cell activation through engagement of the CD19-CD20 complex. Cross-linking of this complex and BCRs lowers the required amount of engaged BCRs for B-cell activation and promotes the differentiation of long-lived plasma cells. These plasma cells secrete antigen-specific antibodies which can either bind to the target cell and activate effector T cells or directly neutralize a virus by inhibiting its uptake. Memory B cells carry antigen-specific receptors and enable long-term immunity by recognizing the pathogen and quickly differentiating into pathogen-specific plasma cells.

VLPs and the Stimulation of Toll-Like Receptors

Toll-like receptors (TLRs) are located within the endosome of DCs, B-cells and other activated cells and recognize certain types of nucleic acids including double-stranded RNA (TLR 3), nonmethylated GC-rich DNA (TLR 9) and 5'-triphosphate RNA (TLR 7/8).

These types of nucleic acids are detected by TLRs as an indicator of infection resulting in an enhanced immune response. In line with this, the co-delivery of these TLR ligands during vaccination experiments results in enhanced B- and T-cell response and enhanced IgG response. Hence, administration of TLR ligands, such as CpG-containing oligodeoxynucleotides (CpG-ODNs), a TLR 9 ligand, might result in a stronger and more protective immune response than using empty particles. Because of their previously described size and structural properties, loading of VLPs with TLR ligands enables a more efficient delivery to B- and DC-cells, compared to simply mixing VLPs, and ligands and strongly reduces side effects of “free” TLR ligands.

Expression Systems to Produce Virus-Like Particles

VLPs can be produced in various systems such as bacteria, yeast, mammalian and avian cells, insect cells, plants and plant cell culture as well as cell-free expression systems. Hence, the origin of the VLP is not necessarily important for the choice of the expression system, because VLPs can be produced in an unrelated system (e.g., VLPs from mammalian viruses in plants, VLPs from plant viruses in bacteria). However, the expression system might influence the similarity of VLP to the original virus, especially regarding post-translational modifications (PTMs) and di-sulfide bond-dependent stability. In this section we briefly discuss the different expression systems and the respective advantages and disadvantages for the production of VLPs.

Bacteria

Bacteria are easy to transform, to cultivate and have a high upscaling potential. As a consequence of this, a high yield of VLPs can be achieved in a short time, making them a cost-effective expression system. However, for some VLPs, PTMs and the integration within the host's endoplasmic reticulum (ER) membrane system are necessary to mimic the antigenicity of the original virus and to achieve product stability. Since bacteria are not able to glycosylate recombinant proteins and do not have an ER, they cannot be used to produce these types of VLPs. Bacteria, furthermore, are not a suitable expression system if the VLP stability depends on the formation of the correct disulfide bonds and they can have issues regarding safety because of the presence of endotoxins in the product.

Examples of VLPs successfully expressed in bacteria include HPV, Hepatitis B virus core antigen (HBcAg) and cowpea chlorotic mottle virus (CCMV) VLPs.

Yeast

Yeasts have similar advantages to bacteria in terms of speed but can be used to produce more complex VLPs, including those from enveloped, glycosylated viruses. The pattern of PTMs, however, differs from mammalian cells. Hence, the product similarity to the original virus might be limited. Metabolic engineering to adopt the yeast glycosylation machinery to a mammalian pattern, might solve this issue in the future.

Various VLPs have been successfully produced in yeast, including, for example, dengue virus, poliovirus, hepatitis B virus (HBV) and HPV VLPs. Gardasil®9 (HPV, Merck), Engerix®-B (HBV, GlaxoSmithKline) and Recombivax HB™ (HBV, Merck Sharp and Dohme) are examples for licensed VLP-based vaccines produced in yeast.

Mammalian Cells

The production of VLPs in mammalian cells leads to the closest similarity of a product compared to all other expression systems, if VLPs of mammalian viruses are being produced. However, the high costs of mammalian cell culture and safety concerns, because of possible product contamination with adventitious mammalian pathogens and toxins, remain a challenge for this expression system.

Different mammalian and avian cell lines have been successfully used to produce a broad range of VLPs like for example dengue virus, poliovirus, foot-and-mouth disease virus (FMDV), human respiratory syncytial virus (RSV), Zika virus, HPV, HBV and chikungunya virus VLPs.

Insect Cells

Insect cells can be used in two ways: Infecting cells with baculovirus-based vectors and stable or transient expression in cells without baculovirus infection. Insect cells can be cultivated to high density and large scale and because the PTMs are similar to mammalian cells, they can have an advantage in product similarity compared to the other non-mammalian systems, if mammalian VLPs are produced. The baculovirus design is very time-efficient, but because enveloped baculoviruses are co-produced during product expression, this system has concerns regarding contamination. The latter does not apply to the baculovirus-free system. Examples of VLPs expressed in insect cells include Ebola virus, dengue virus, poliovirus, FMDV, chikungunya virus, human immunodeficiency virus 1 (HIV1), Cervarix® (HPV, GlaxoSmithKline), influenza virus VLPs consisting of haemagglutinin (HA) and matrix protein 1, rabbit hemorrhagic disease virus and porcine parvovirus VLPs.

Plants and Plant Cell Culture

Plants and plant cells can be used to express a broad range of VLPs using two different strategies: stable transformation and transient expression.

In general, plants and plant cell culture are highly scalable but, depending on the method used, the advantages and disadvantages in other areas differ. Stable transformation is time-consuming, and the product yields are usually lower compared to transient expression systems. However, once an elite event is available, whole plants can be the cheapest expression platform, because they only require soil, water and light to grow. By contrast, plant cell culture requires growing media and bioreactors making it more expensive. Another advantage of stable transformed plants and plant cells is that they do not contain endotoxins and are free from mammalian pathogens, a safety benefit of this method. Transient expression leads to higher yields is faster and is essentially a batch process. However, agrobacteria have to be cultured in large quantities and, for large-scale production, plants must be infiltrated using vacuum infiltration systems. This makes it more expensive and, because agrobacteria are used, the endotoxin level of the final product must be monitored. The currently most promising system to produce VLPs in plants is transient expression in *Nicotiana benthamiana*.

The range of plant made VLPs includes, for example, Bluetongue virus (BTV), nervous necrosis virus (NNV), human norovirus, poliovirus, HBcAg VLPs and enveloped influenza VLPs displaying HA (Medicago, Canada). Structural analysis of polio type 3 and NNV revealed that assembly of VLPs in plants lead to high structural similarity compared to the native virus (Fig. 3). Medicago's influenza VLPs represent the first plant-made VLP-based vaccine in Phase III clinical trials and in early 2020 the company announced the successful production of SARS-COV2 VLPs, 20 days after they obtained the necessary genes showing the potential of plants as a rapid VLP production platform.

Cell-Free Expression Systems

Cell-free protein synthesis (CFPS) is based on the use of cell extracts, rather than on living cells. This has the advantage that reaction conditions can be easily controlled and adjusted. CFPS is not sensitive to toxic products and endogenous DNA and mRNA can be removed prior to VLP production, preventing the expression of unwanted proteins. Furthermore, unnatural- or radioactively labeled amino acids can easily be added to the reaction mix for monitoring VLP synthesis. However, upscaling of this system is an issue and is not yet possible at industrial scale.

Cell-free extracts can be based on cell lysates of different organisms and a range of CFPS like *E. coli*, rabbit reticulocytes, wheat germ, insect cells and Yeast *Kluyveromyces* are commercially available. *E. coli* and yeast based CFBS have been successfully used to produced VLPs of different viruses and bacteriophages including M2 bacteriophage, Q β bacteriophage, HBcAg and HPV.

Virus-Like Particles as Nano-Carriers

Besides their direct use as vaccines, VLPs can be used as antigen and/or substance carriers for the development of vaccines against different pathogens and for therapy of chronic infections or cancer. The carrier and therapeutic VLPs do not have to be based on human viruses, but can be derived from bacteriophages, insect-, animal- and plant viruses. Indeed, the use of non-human viruses as nano-carriers has the advantage that there is no pre-existing immune response, such as the presence of neutralizing antibodies against the carrier. Such pre-existing immunity, arising through infection or vaccination, might reduce the delivery efficiency of the VLPs. However, the most important feature for a VLP as a nano-carrier is high stability and structural flexibility to allow antigen display on the particle surface and the loading of the particles. The combination of both peptide display and loading of particles allows the direct targeting to specific cells when a targeting molecule is displayed on the surface of the VLP. This is mainly exploited in cancer therapy research, where VLPs are loaded with anti-cancer drugs and molecules targeting specific cancer cell receptors are presented on their surface. Frequently used and analyzed VLPs include rabbit hemorrhagic disease virus (RHDV), bacteriophage Q β , bacteriophage AP205, bacteriophage MS2, cucumber mosaic virus (CMV), cowpea mosaic virus (CPMV) and HBV (HBcAg or surface antigen (HBsAg) VLPs). Examples for the successful use of antigen display are the malaria vaccines RTS,S/AS01 Mosquirix™ and R21. These vaccines are based on HBsAg VLPs displaying an antigen consisting of 19 NANP repeats from the central repeat region and the C-terminal region of circumsporozoite protein (CSP) of *Plasmodium falciparum*.

Conjugation of antigens to VLPs is possible using different methods such as genetic integration, chemical conjugation and conjugation via the SpyTag/Catcher system, while loading of VLPs can be achieved by in vitro assembly, pH shift and using the natural permeability of the VLPs.

Conjugation of Antigens and Virus-Like Particles

Genetic fusion

The easiest way to conjugate antigens to VLPs is through integration of the DNA sequence of the respective antigen into the viral sequence. The advantage of genetic fusion compared to chemical conjugation or the SpyTag/SpyCatcher system is that only one construct has to be expressed and purified and no in vitro conjugation after purification is necessary. The antigen of interest can be inserted at different locations within the coat protein such as the C-terminus, N-terminus or in exposed loops on the VLP

Fig. 3 Examples of plant-made VLPs (not shown to scale). The upper panel shows the external surface and the lower panel the inner surface. Structure determination was carried out by cryo-electron microscopy. Nervous necrosis virus (3.7 Å): The NNV viral asymmetric unit is composed of three copies of the coat protein and three P-domains of the capsid protein interact and form spikes on the particle surface (chain A=light green, chain B=cyan, chain C= dark green). Polio type 3 (3.6 Å): Four structural proteins form the capsid protein: VP1 (yellow), VP2 (orange), VP3 (red) and VP4 (green). Even though VP0 is not cleaved into VP2 and VP4 in plants, the surface structure of assembled VLPs is nearly indistinguishable from wild type virus. Empty cowpea mosaic virus VLPs (2.3 Å): 60 copies of large (green) and small (white) coat protein assemble to T = 3 icosahedral empty VLPs.

surface (e.g., L1 loop on RHDV or the major immunodominant region (MIR) on HBcAg VLPs). For RHDV VLPs it was shown that antigens can be integrated at all three positions at the same time. This allows antigen display on the inside of VLPs, as described for RHDV and BTV. This might be especially of interest for the protection of unstable peptides inside the particles.

However, the genetic fusion strategy has limitations, because insertion of larger antigens or antigens with unfavorable charges can alter the VLP conformation and subsequently the assembly and stability of the particles. Different strategies have been developed to improve the tolerance of VLPs for the presence of larger antigens such as the creation of mosaic particles, the split core and tandem core technology for HBcAg.

To produce mosaic VLPs, the modified viral protein containing the antigen and unmodified viral protein are co-expressed such as in the case of HBcAg/HBsAg proteins. This technology allowed the introduction of up to 213 amino acids of a hantavirus antigen at the C-terminus of a truncated version ($\Delta 144$) of HBcAg. A drawback of mosaic particles is that the ratio of the modified to unmodified protein in the VLPs cannot be easily controlled and thus the VLPs might only contain small amounts of antigen-presenting subunits and some VLPs may not contain any antigen.

Further improvement of antigen integration by genetic fusion was achieved with the split- and tandem core technology. These technologies allow the integration of larger antigens and help to overcome conformational restrictions. The split core technology is based on an artificial separation of the c/e1 loop of HBcAg MIR by the insertion of a stop and a start codon between amino acid 79 and 80, resulting in two open reading frames coreN and coreC without alteration of VLP assembly. The antigen of interest can then be fused to either the C-terminus of the N-terminal half monomer, or the N-terminus of the C-terminal half monomer. The tandem core technology is based on the production of a HBcAg dimer as a single polypeptide chain by fusion of two HBcAg open reading frames. The respective HBcAg proteins are covalently linked by a flexible linker which allows the insertion of large heterologous sequences in only one of the two MIRs in each spike resulting in a higher conformational tolerance of the VLPs after integration of larger antigens or whole proteins such as GFP.

Chemical and affinity conjugation

Chemical conjugation allows the fusion of not only VLPs and larger protein-derived antigens, but also their fusion to non-protein targets, cyclic peptides and whole proteins. This strategy is based on covalent linkage of heterobifunctional conjugation of two

distinct reactive groups that couple two different residues, one on the VLP surface and one on the antigen. Appropriate reactive groups on the carrier VLP are usually the ϵ -amino group of lysine, the carboxyl groups of glutamic and aspartic acids or the sulphhydryl of cysteines. Conjugation of VLP and antigen is then possible via these reactive groups. If the required reaction partner is not naturally present on the VLP surface it can be engineered into the subunits as shown for HBcAg, bacteriophage MS2 and CPMV.

One example of chemical conjugation of a VLP and an antigen is the use of Sulfo-succinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (Sulfo-SMCC) and a partner that contains a free sulphhydryl group or was treated with *N*-Succinimidyl S-Acetylthioacetate (SATA) to induce the formation of sulphhydryl groups. Treatment of VLPs with Sulfo-SMCC results in maleimide-activated particles which can then be mixed with antigens containing the sulphhydryl group resulting in covalent, irreversible binding of these groups (Fig. 3).

Apart from covalent binding, noncovalent affinity conjugation can be used to fuse VLPs and antigens. This is based on strong interactions between certain partners, such as that between biotin and streptavidin. Another example is the use of a peptide tag that binds to the MIR of HBcAg particles and is based on the natural interaction between HBcAg and HBsAg. However, for the second example a sucrose gradient ultracentrifugation step disrupted the particle-epitope binding indicating instability of this interaction.

Even though chemical conjugation allows the displaying of larger antigens and non-protein conjugation partners, it has drawbacks for downstream processing, because it requires several more steps than using genetic integration thus making it time-consuming and expensive. Chemical conjugation requires the expression and purification of VLPs and conjugation partner in separate steps and after purification one or both partners require chemical activation. The chemical activators have to be removed from the VLP or antigen samples in an additional purification step before the conjugation reaction and finally, uncoupled antigens and VLPs have to be separated.

The SpyTag/SpyCatcher system

Similar to the chemical conjugation approach, the SpyTag/SpyCatcher system is based on the affinity of reactive groups and allows the conjugation of larger antigens to VLPs. In this case, the reactive groups were identified in the CnaB2 domain of the FbaB protein from *Streptococcus pyogenes*. SpyTag is a 13 amino acid long peptide containing aspartic acid as one reactive group, while SpyCatcher is a protein with a size of 12.3 kDa containing a reactive lysine group and a catalytic glutamic acid. In the presence of each other, the carboxyl group of the reactive aspartic acid and the ϵ -amino group of the lysine form a covalent isopeptide bond. Genetic integration of the SpyTag at the N-terminus of a peptide and SpyCatcher on the surface of a VLP (or vice versa) allows the conjugation of the partners. This conjugation can be achieved after their individual expression and purification, followed by an *in vivo* reaction when both components are mixed, or by simply co-expressing the two respective constructs in a single cell. Co-expression might be beneficial, because it is cost saving and simplifies the downstream processing by reducing the number of purification steps required. In a proof of concept study it was shown that co-expression and *in vivo* conjugation of HBcAg VLPs (SpyCatcher) with GFP and P24 respectively (both SpyTag) led to the successful conjugation of VLPs and the respective partners in *Nicotiana benthamiana*. Even though the SpyTag/SpyCatcher system can be very efficient, it is still necessary to distinguish and separate conjugated and non-conjugated partners. This applies for both *in vivo* and *in vitro* conjugation and has to be considered when using this method.

Loading of Virus-Like Particles by Encapsulation

As well as displaying antigens on the outer surface of VLPs, materials can also be incorporated inside the particles. This process is called encapsulating and is not limited to peptides, but also whole proteins, nucleic acids, inorganic compounds and other pharmaceutical substances like cancer drugs can be encapsulated. The main advantages of this delivery system are an improved delivery, the adjuvant effect of the VLPs and the protection of conjugation partners inside of particles against for example proteolysis or thermal denaturation. A broad range of VLPs was so far analyzed for this strategy including VLPs based on bacteriophages (e.g., MS2, Q β , P22), plant viruses (e.g., hibiscus chlorotic ringspot virus (HCRSV), cowpea chlorotic mottle virus (CMV), tobacco mosaic virus), animal viruses (e.g., bluetongue (BTV)) and human viruses (e.g., HBV, SV40).

Two main strategies are available to load particles: statistical- and direct encapsulation. Both strategies can be used *in vitro* and *in vivo*, while for statistical encapsulation the *in vivo* approach is more common.

For statistical encapsulation, VLPs or viral particles are first produced, purified and then disassembled by a pH shift into the viral capsid proteins. If present in the sample, nucleic acid can be removed before cargo and capsid proteins are mixed. The VLPs can reassemble after an additional pH shift and some of the cargo in the sample mix gets encapsulated. For smaller molecules disassembly of VLPs is not obligatory, because they may diffuse through openings in the viral shell, which then can be "closed" by a pH shift resulting in trapping of the cargo inside the particles. However, this strategy requires large amounts of VLP capsid proteins and cargo, and the loading cannot be precisely controlled and might not be reproducible in terms of the amount of encapsulated material. This loading strategy also has requirements regarding to charge and size of the molecule. If the molecule is too small, it may leak out of the VLP shell and for some plant viruses, such as hibiscus chlorotic ringspot virus (HCRSV) and CCMV, it is also necessary that the cargo has a negative charge. Both requirements can be addressed using polyacid association, a process where semi stable complexes between large molecular weight polyacids and the smaller cargo are formed resulting in higher sized aggregates with a negative charge. This enables encapsulation of smaller, positive charged molecules like cancer drugs without altering the deliverability.

Direct encapsulation is similar to surface conjugation and can be based on genetic integration of the sequence of interest within the respective part of the viral genome, the use of specific tags or chemical interactions between amino acid residues of the cargo and the inside of the VLPs. As described for the statistical encapsulation, VLPs or viral particles can be disassembled, mixed with tagged cargo and then reassembled resulting in integration of the tagged material. Furthermore, tagged peptides or proteins can be co-expressed with the capsid proteins or directly genetically fused, saving the *in vitro* steps. This strategy was successfully used to encapsulate proteins and antigens into VLPs of BTV, P22 and RHDV VLPs.

VLP-Based Vaccines for Humans

HPV and HBV

Licensed VLP-based vaccines are currently available against human papilloma- (HPV) and hepatitis B virus.

HPV is a causative agent of cervical-, vaginal-, vulvar, penil-, anal- and oropharyngeal cancer and 200 subtypes of HPV have been isolated. Out of these 200 subtypes, 13 are known as high risk HPV (hrHPV) and 7 of hrHPV (16/18/31/33/45/52/58) are responsible for 98% of all cancers caused by HPV. Low risk HPV subtypes do not cause cancer but induce the formation of genital warts, where subtype 6 and 11 are responsible for 85% of cases. However, the risk of HPV infection can be minimized by vaccination. The current licensed vaccines are based on VLPs which are produced by expressing the L1 coat protein of HPV types in yeast (Gardasil®, Gardasil9®) or insect cells (Cervarix®). Cervarix® is a bivalent vaccine containing VLPs of subtype 16 and 18, while Gardasil and Gardasil9 are quadrivalent (6/11/16/18) or nonavalent (6/11/16/18/31/33/45/52/58) respectively. Immunization with VLPs leads to high antibody titer and long-term protection of vaccinated individuals. While the L1 protein differs between HPV subtypes, the minor capsid protein L2 is highly conserved. However, L2 cannot form VLPs, but L2 display on other VLPs such as Q β - or MS2 is possible and currently pre-clinically tested.

Vaccines against Hepatitis B virus have been available since the 1980s. The first generation of these vaccines were HBsAg particles isolated from the blood of infected individuals. Because of issues like biosafety and tolerability the second generation of vaccines was developed. These vaccines are based on the recombinant expression of HBsAg protein in yeast and the isolation of VLPs. This generation includes licensed vaccines like for example RecombivaxHB or Engerix-B. These vaccines are efficient, safe and have significantly reduced HBV prevalence worldwide. A third generation VLP based vaccine, Sci-B-Vac™ which is produced in Chinese hamster ovary (CHO) cells, is a further improvement. The recombinant HBsAg VLPs mimic three antigenic sites (S, PreS1 and PreS2) instead of only one (S) in the second generation. Sci-B-Vac™ need lower doses compared to the second-generation vaccines and also showed an improved response in obese or older people and in immunocompromised patients, patients with transplants or dialysis and low responders marking a further improvement in HBV vaccination.

Influenza

Besides the licensed examples above, a range of VLP based vaccines is currently in clinical trials. Two examples are Medicago's pandemic influenza vaccine, currently in clinical phase II, and a seasonal influenza vaccine which went through clinical phase III trials and was accepted for scientific review by Health Canada in October 2019 and could be licensed and available in 2020/2021. Both vaccine candidates are produced in plants. The quadrivalent vaccine against seasonal influenza contains VLPs of two strains of influenza A and B respectively, while the pandemic approach uses the respective sequence of the pandemic strain. Influenza VLPs can be produced by the expression of the hemagglutinin (HA) antigen, resulting in assembly of VLPs containing a lipid bilayer envelope. They have different advantages compared to currently licensed products like a short response time and scalability. The response timeline is 3 weeks from obtaining the HA sequence to the first purified VLPs and a production rate of about 1 million doses per month was described. Furthermore, the plant-based recombinant VLP vaccine targets wild-type HA sequences, in contrast to influenza strains grown in eggs or tissue culture that may have mutated during culture.

Polio

Poliovirus is the causative agent of poliomyelitis, a disease which can lead to paralysis of limbs or even death. Introduction of live attenuated (OPV) and inactivated polio vaccines (IPV) led to a 99% decrease in polio cases and wild-type polio type 2 and 3 were declared eradicated by the world health organization (WHO) in 2016 and 2019, respectively. In 2019 about 125 cases of wild type polio 1 infections were recorded, while about 245 cases of vaccine-derived poliomyelitis occurred. These cases are mainly caused by reverse mutation of attenuated polio strains in OPV resulting in regained pathogenicity of the attenuated virus. Thus, while OPV and IPV are efficient and successful vaccines, they are not suitable for the final eradication of poliovirus. Hence, a virus-free polio vaccine is of great interest and VLPs are a promising candidate vaccine.

However, the production of Polio VLPs is not straight forward, because empty polio capsids based on wild-type sequences are antigenically unstable and switch from D to C antigenicity, which makes them unable to induce protective immunity and thus are unsuitable for use as vaccines. This issue was solved by introducing stabilizing mutations into structural proteins resulting in predominant D antigenicity of VLPs. Polio VLPs can be produced by expressing the stabilized structural polyprotein P1 and the viral protease 3CD in various expression systems such as plants, yeast, insect cells, mammalian cells and cell free expression systems.

Fig. 4 Methods for antigen display on the surface of VLPs. Genetic integration of the antigen sequence (orange) into the sequence encoding the viral capsid protein is possible at multiple sites, including the N-terminus, the C-terminus or in exposed regions on the VLP surface (e.g., c/e1 loop of HBcAg). Chemical conjugation is based on reactive groups in the two partners. For chemical conjugations the two partners are produced separately and VLPs can be maleimide activated using Sulfo-SMCC which then reacts with the free sulfhydryl group on the antigen. The SpyCatcher/SpyTag system is based on a similar principle. The 13 amino acid long SpyTag carries an aspartic acid residue while the SpyCatcher protein contains a reactive Lysine and a catalytic glutamic acid residue. Once SpyTag and SpyCatcher interact the aspartic acid and lysine irreversibly form an isopeptide bond. SpyTag-Spy catcher reaction with kind permission of PNAS (Zakeri *et al.*, 2012. Peptide tag forming a rapid covalent bond to a protein, through engineering a bacterial adhesin. PNAS 109 (12) 4347–4348).

In plants, efficient processing of the P1 polyprotein into VP1, VP3 and VP0 was confirmed and assembly of the structural proteins resulted in VLPs almost indistinguishable from wild type polio virus (Fig. 4). Preclinical tests in transgenic polio receptor-expressing mice showed that VLPs protected mice from a polio challenge as efficiently as the IPV control. However, this is only true for Polio type 1 and 3, while the production of stable Polio type 2 VLPs remains a challenge in all expression systems.

VLPs as Cancer Vaccines and Therapeutics

VLPs have been intensively investigated for their suitability as a cancer vaccine and as cancer therapeutics. Antigen display and loading of particles, as well as the use of empty CPMV VLPs, have shown great potential in both fields and multiple studies are currently in preclinical, clinical phase I and clinical phase II trials.

For the vaccine approach, the protection induced by VLPs is based on T cell and/or antibody responses. Various VLPs such as RHDV, polyomavirus, cucumber mosaic virus (CMV), CPMV, HBcAg, bacteriophage Q β , bacteriophage MS2 and bacteriophage AP205 have been analyzed for treatment of different cancers including melanoma, breast cancer, pancreatic cancer, cervical cancer and hepatocellular carcinoma. Three different strategies have been mainly analyzed so far: presentation of a single antigen, display of multiple antigens for a certain cancer type and the use of empty VLPs without the presentation of any antigens. Furthermore, these strategies can be combined with the use of different adjuvants, TLRs or checkpoint inhibitors to optimize immunogenicity. The use of multiple antigens seems to be beneficial compared to a single antigen, because of possible outgrowth of antigen-loss tumor cells and higher efficiency. This was shown for RHDV VLPs displaying epitopes from murine topoisomerase IIa and survivin, either in a mono- or multi-target form. Here, the multi-target form significantly prolonged the vaccine-induced remission period compared to the mono therapy approach. Interestingly, empty CPMV and Q β bacteriophage VLPs loaded with A-type CpGs showed promising results in the treatment of different melanoma types without presenting any heterologous antigens. *In situ* vaccination of a lung melanoma with empty CPMV VLPs led to systemic anti-tumour immunity against B16F10 melanoma. This shows that VLPs, even if they are derived from plant viruses, can be highly immunogenic without displaying specific antigens or carrying any adjuvants.

As described before, VLPs can also be loaded with nucleic acids (e.g., mRNAs, micro RNAs, small interfering RNAs), peptides and other pharmaceutical substances as smaller molecules such as cancer therapeutics (e.g., taxol and doxorubicin). Additionally, they can be designed to target specific cancer cells, while leaving healthy cells unaltered. This is possible by conjugation of VLPs with specific targeting ligands such as glycans, receptor-binding ligands (e.g., folate and transferrin), specific antibody fragments

Fig. 5 Cell-specific cargo delivery using VLPs. VLPs are loaded with cargo and display cell-specific target ligands that recognize specific cell surface markers. After binding of VLPs to the markers, endocytosis is triggered (1) and after the VLPs escape from the endosome (2) they get degraded and release the cargo into the cytosol of the target cell (3).

(e.g., anti-HER2 to target melanoma cells or Trastuzumab for breast cancer cells) and RNA- and DNA aptamers (e.g., DNA aptamer with affinity to target tyrosine kinase 7 receptors on Jurkat leukemia T cells).

However, using nano particles as a delivery system has certain challenges. The particles need to remain stable to protect the cargo (e.g., to shield the RNA from RNases) and to avoid nonspecific engulfment by phagocytosis. After endocytosis into the target cell, the carrier needs to be able to escape from the endosome (Fig. 5), get degraded and release the cargo into the cytosol of the host cell. Hereby, the release of the cargo at once is more efficient than a slow release (as described for polymer nano particles). It was shown in animal models and cell culture that a range of VLPs like CCMV, CPMV, Q β , MS2 and P22 meet these criteria and that VLPs are promising nano carriers for cancer treatment using cargo delivery inside of particles.

Introduction

When we began writing this article in April/May 2020, we were in the middle of the first 'lockdown' in the UK, a quarantine measure adopted in most countries in attempts to contain the exponentially spreading viral disease we call COVID-19. Caused by a novel strain of coronavirus, named SARS-CoV-2, the COVID-19 pandemic, which was first recognized in Wuhan, China in December 2019, had by May 2020 knocked trillions of dollars off international markets and drastically changed the way we lived, at least for the time being. Daily life and livelihoods have been paralyzed by the mandatory, but unfortunately necessary, quarantine measures, separating us from our families, friends and colleagues. Hospitals were overflowing while stores, theaters and restaurants have been closed, many already bankrupt.

Months later, as this article goes to print (November 2020), the death toll of COVID-19 has exceeded one million, and there are no signs that the pandemic is abating, let alone ending. Indeed, some medical historians contend that epidemic endings are a form of collective amnesia, transmuting the disease that remains into merely someone else's problem. The current coronavirus pandemic is neither the first, nor likely the last, viral visitation that humans have experienced on a mass scale. The impact of viruses on our lives predates our knowledge of their existence, as manifested in the way societies have responded to viral epidemics regardless of whether the cause was known at the time.

Often described as entities hovering on the threshold of life, viruses are found in parasitic, commensal or symbiotic association with the entire range of living organisms from single celled Archaea and bacteria to plants, animals and humans. They play a dual role in the laboratory, both as objects of investigation and as experimental tools. They have greatly enhanced our understanding, not only of human disease, but also of the living world more broadly.

In this article we consider the tremendous impact, past and present (and undoubtedly future), of viruses on humans, in both science and society. Recognizing that every interaction is a two-way street, we also remark on the ways that human activities – both deliberate, e.g., in the way we use them in the laboratory, and unknowing, through lifestyle choices – have affected viruses. We also examine how the modern, interconnected world has little resilience in terms of socio-economic consequences of the emergence of a pandemic virus.

Virus: Meanings and Metaphor

Expressions such as "going viral" are so widely used today that it is easy to forget that viruses have a narrower, more precise meaning for scientists than for the public at large. In popular usage, the term is frequently elided with any invisible germ (much to the irritation of virologists), but this imprecision is not a serious matter unless it leads to inappropriate treatment of virus infections by antibiotics that target bacteria.

Etymology and Evolution of the Meaning of Virus

The notion of contagion by invisible agents specific for different diseases was expounded by Girolamo Fracastoro in 1546, and the word 'virus' appears to have been imported into the English language from Latin as a word for poison or venom sometime in the sixteenth century. One of the earliest documented references is in Edward Jenner's classic 1798 report on the prevention of smallpox. Jenner's use of the word virus was not precise, and it was not until the late nineteenth century in the wake of the germ theory that the word virus came to mean a type of disease agent. As the ability of bacteria to cause specific infectious diseases, e.g., tuberculosis, cholera and anthrax, was established, scientists found other infectious diseases from which they could not isolate bacteria. The two earliest examples were mosaic disease of tobacco plants by Dmitri Ivanowski (1892) and foot-and-mouth disease of cattle and swine by Friedrich Löffler and Paul Frosch (1898). They still considered the causative agents to be bacteria, only smaller than known ones. But in 1898, Martinus Beijerinck proposed that the tobacco mosaic agent (what we now call tobacco mosaic virus, TMV) is distinct from bacteria in being somehow dependent for its multiplication on the cells of its host. He described TMV as a *contagium vivum fluidum*, Latin for a 'living soluble contagion'. Without adequate techniques to test it, Beijerinck's idea only gained traction 30 years later, when it helped establish virology as an independent discipline in its own right.

The next couple of decades witnessed many discoveries of viruses and viral diseases, as well as contentious debates over the nature of viruses as living versus non-living organisms. Virological concepts deepened with the development of new instruments and methods of visualizing and cultivating viruses, as well as the emergence of molecular biology, which gave scientists both new

Fig. 1 Electron micrograph of a human common cold coronavirus virus particle (~ 100 nm diameter) of isolate B814 taken by June Almeida in 1966 using the new technique of “negative staining”. It was the ‘characteristic fringe of projections which are rounded or petal shaped, recalling the solar corona’ that led to the adoption of the name Coronavirus for this family in 1968. These projections depict the “S” envelope glycoprotein. Reproduced by permission of the Microbiology Society. From Almeida, J.D., Tyrrell, D.A.H., 1967. The morphology of three previously uncharacterized human respiratory viruses that grow in organ culture. *Journal of General Virology* 1 (2), 175–178.

techniques and a new language. In the 1950s, the French microbiologist, André Lwoff, formulated the modern definition of viruses as ‘obligate intracellular parasites’ composed of a single type of nucleic acid (either DNA or RNA) encased in a protein coat.

Virus as Metaphor

It seems a valid description to call self-propagating malware a “computer virus”, given that it can spread rapidly from one computer to another, reproducing itself and lead to malicious outbreaks. Similarly, descriptions of rumors on social media going “viral” are apt. They allow “pathogenic” entities such as fake news and conspiracy theories to germinate, propagate and become pandemic, such as SARS-CoV-2 escaping from a germ warfare laboratory – or the influence of G5 networks on its spread. Similar conspiracy theories were applied to the emergence of HIV and other viruses in the past.

In times of pestilence, myths of blame or denial often arise. Among the powerful, the blame game for viruses is evident today. As for denial, the former President of South Africa, Thabo Mbeki, became convinced by the notion propagated on the web that HIV did not cause AIDS, and he considered that anti-retroviral drugs were a ruse by Western pharmaceutical companies to profit at Africa’s expense. His ban on providing anti-retrovirals is estimated to have cost 350,000 lives.

Viruses and Science

The relationships between science, viruses and society are complex. Science is the study of the natural world, by which token viruses fall under its ambit. But whereas virology only became a scientific discipline in the twentieth century in the wake of scientific discoveries mentioned earlier (and reviewed by David Rowlands in this volume), viruses themselves have shaped general science for much longer, just as they have influenced society more broadly. Medical specialties such as epidemiology and public health owe much of their

development to infectious diseases we now know to be caused by viruses, as do such medical technologies such as vaccination. The discovery of viruses stimulated a synergistic development between advances in virology and the broader development of science and technology.

Impact of Science and Technology on Virology

The expansion of virology owes a lot to the invention and development of novel instrumentation and laboratory techniques. Many of these tools came from disciplines outside the bounds of biology; from biophysical and engineering sciences and from analytical chemistry. Here too there was synergy, for the viruses spurred improvements of laboratory techniques as well as instrument design.

It was the development of improved bacteriological filters by Charles Chamberland in 1884, originally intended for purifying water, that enabled the discovery of TMV and foot mouth disease virus. The refinement of filtration – more accurately – ultra-filtration, also provided the means for determining the size of virus particles. For example, the British physical chemist, William Elford, developed a series of filters with graded pore sizes to determine the dimensions of a number of different viruses.

Elford also played a pioneering role in harnessing the ultracentrifuge, invented in 1925 by Theodor Svedberg in Sweden, which allowed the separation and concentration of virus particles of different densities. Ultracentrifugation became widely used as both an analytical and preparatory tool in virology, which in turn led to innovations in the design of future generations of the instrument. In 1936, the American physical chemist, Wendell Stanley, used ultracentrifugation to concentrate and purify TMV. He successfully crystallized the purified TMV and used X-ray crystallography to discern its structure thinking it contained only protein, but Frederick Bawden, Norman Pirie and colleagues soon revealed its all-important RNA core. As Bawden later remarked, “before 1936 it was tacitly assumed that *all* viruses were incompressible spheres”. The needle-like crystals of TMV showed otherwise.

The most dramatic change was wrought by the invention and development of the electron microscope, just as the optical microscope had done for bacteria in the seventeenth century which, in Robert Hooke’s words “opened up a whole new invisible World discovered to the Understanding”. The first electron microscope was designed in 1931 by Ernst Ruska, a German electrical engineer and it was his brother, Helmut Ruska, a medical student at that time, who grasped the potential for the new technology in biomedicine. He pursued the visualization of “sub-microscopic agents of disease” and produced the first electron-microscopic images of poxviruses in 1938. Electron microscopy proved a particularly synergistic development with virology; although it stood supreme in the visualization of viruses, it also gained in return, especially in areas of specimen preparation and staining technology (Fig. 1).

While crystallization and electron-microscopy gave scientists a handle on the physical and chemical properties of viruses, they yielded little information about their behavior and biology. The biggest hurdle in this arena was posed by the inability of scientists to isolate and propagate viruses in the laboratory as they could bacteria, because as we now know, viruses are obligate parasites that need a living host cell in order to multiply. With the technique for plating lawns of bacteria in petri dishes already in place, the first viruses to be successfully cultured in the laboratory were the bacteriophages, recognized by the ability to form discrete clear plaques of lysed bacteria. The serial dilution of the “phage” allowed accurate titration and biological cloning, as did titration of TMV on leaves. The cultivation of animal viruses proved more difficult until the propagation of viruses on the chorio-allantoic membrane of embryonated bird’s eggs by Ernest Goodpasture in the United States and Macfarlane Burnet in Australia. Virus propagation in cell cultures was first exploited for polio virus by John Enders, Thomas Weller and Frederick Robbins in 1949.

To illustrate the increasingly rapid pace of technology in virology, let us consider the emergence of novel pathogenic viruses over the past 40 years. Following the appearance of AIDS in 1981, it took two years to identify the virus, HIV-1, and a year more to persuade the world by independent studies that the correct culprit had indeed been found. A further 18 months led to the roll out diagnostic tests based on serology and to the cloning and sequencing of the HIV-1 genome. We had to await the development of the polymerase chain reaction (PCR) technique to monitor viral load in patients. Anti-viral therapy to HIV-1 only became effective in 1996 with the introduction of a combination of drugs targeting more than one step in the replication cycle.

When SARS emerged in 2003, it took less than 2 months to characterize the virus as a member of the coronavirus family, whereas in January 2020, Chinese scientists obtained the full genetic sequence of SARS-CoV-2 from a COVID-19 patient within 2 days. They devised a reliable PCR test to detect infection within a week, although diagnostic tests for SARS-CoV-2 antigens and antibodies have taken a little longer, especially for large scale usage. Pseudotype viruses, based on retrovirus or rhabdovirus vectors incorporating reporter genes that bear the SARS-CoV-2 envelope “S” (spike) glycoprotein, are providing highly sensitive and specific virus neutralization assays without the need for high level containment facilities. These are being employed to study whether recovered patients have protective immunity and as a preliminary test of vaccines based on antibody responses.

DNA sequencing has become ever higher in throughput. In 1987, it was considered quite an achievement to gain the complete DNA sequence of the 150k kilobase genome of human cytomegalovirus. Compare that to today, when a cohort of 1000 COVID patients and healthy controls are each having their total host genome sequenced to identify possible genetic risk factors, and to see if more severely affected people are infected with more virulent variants of SARS-CoV-2.

Virology has benefited from advances in computational sciences, such as bioinformatics, sequence analysis, “big data” and mathematical modeling. The science of tracking and intervening in the course of epidemics using mathematical models began in earnest in 1760, when the Swiss mathematician, Daniel Bernoulli, showed how large-scale variolation against smallpox would

benefit not only the individual but also the population at large, which was the origin of the concept of herd immunity. Had the physicians attending his lecture to the Academie Française heeded his message, Louis XVth and many courtiers at Versailles might not have succumbed to smallpox during the epidemic in May 1774.

Impact of Viruses on Science

Due to their unique characteristics, viruses have wielded a huge influence on advances in biology and medicine, exploited as tiny, precise tools to reveal the inner workings of the cells they infect. One rough measure of the impact of viruses on science can be garnered from the number of Nobel Prizes awarded in Medicine & Physiology and in Chemistry to discoveries made about and through viruses (Table 1).

Leading the way as a scientific tool were the bacteriophages, to which the physicist-turned-biologist, Max Delbrück turned his attention as a means to study genes at the individual and molecular level. Together with Salvador Luria and Alfred Chase, Delbrück created the famed “American Phage Group” which throughout the 1940s laid the foundations of modern molecular biology and set the scene for studies in DNA replication, recombination, and protein studies. Meanwhile André Lwoff and colleagues at the Institut Pasteur in Paris studied another group of bacterial viruses known as the lysogenic or temperate phages, which can persist in latent form within the host bacterium. Lytic and lysogenic phages played a crucial role in defining viruses as

distinct from other replicating entities. Jacques Monod and François Jacob employed phages to study mechanisms of genetic regulation and established much of our basic knowledge of universal rules of replication, transcription and translation.

TMV was aptly dubbed by the virologist Heinz Fraenkel-Conrat as “almost always the first” in virology, being the first, as mentioned, to be crystallized, and a major player in the commercial development of the ultracentrifuge and electron microscope. Animal virology, too, led to important discoveries in other areas such as the inner workings of cells and of genes. Split genes with introns and RNA splicing was revealed in 1977 through studies by Phillip Sharp and by Richard Roberts of transcription of human adenovirus type 2. Enveloped viruses, such as the DNA virus, vaccinia, and RNA viruses, such as influenza virus and alphaviruses (Semliki Forest and Sindbis viruses) have been excellent tools exploited by the Finnish virologist, Ari Helenius, and others to probe endocytosis, membrane fusion, conformational changes, secretory pathways, and post-translational modification of proteins like glycosylation. Paramyxoviruses like Sendai virus, which enter cells at the cell surface rather than through receptor-mediated endocytosis, were used to effect cell-to-cell fusion by inactivating the RNA genome without affecting envelope glycoprotein function. Inactivated Sendai virus was exploited to fuse human cells with murine cells by John Watkins and Henry Harris in pioneering studies of human somatic cell genetics.

It was not until the 1950s that Renato Dulbecco and Marguerite Vogt developed plaque assays for lytic viruses on animal cell monolayers beneath an agar gel overlay. From the mid-1960s to the 1980s oncogenic viruses played the leading role in opening up the molecular biology of cancer, including the discovery of oncogenes, which promote malignancy, and of tumor suppressor genes, which keep it in check. Rous sarcoma virus (RSV), the prototype retrovirus, was discovered by Peyton Rous in 1911, but was largely ignored by cancer experts for many decades, who did not believe that the agent was a virus until, in 1958, Harry Rubin and Howard Temin developed an in vitro cell transformation assay for RSV. Thus, oncogenic viruses began to reveal their secrets, including reverse transcriptase in 1970, the integration of viral genomes into host DNA, and the identification of viral genes with oncogenic potential. Reverse transcription permitted the synthesis of complementary DNA from spliced messenger RNA and hence led to the manufacture in bacteria of eukaryotic proteins and biological pharmaceuticals.

The cellular origin of oncogenes – genes that induce tumors – was first revealed by Harold Varmus, Michael Bishop and colleagues with the transforming *src* gene of RSV, and its gene product became the first known tyrosine kinase. The host homologs of most of the 30 or more oncogenes discovered in various oncogenic animal retroviruses, eg., *abl*, *myc*, *ras*, have important roles in cancer signaling pathways. Several have become successful targets for anti-cancer therapy. Conversely, the discovery of endogenous proviruses in the germ line of chickens and mice led to the realization that a substantial proportion of vertebrate host genomes is represented by ‘fossil’ retroviruses; approximately 8% of human DNA comprises retroviral genomes, some of which have been repurposed by the host for essential functions such as placental development.

Another important milestone with oncogenic viruses was the discovery of the tumor suppressor protein (TSp53) in cells transformed by simian 40 virus (SV40). In 1979, David Lane and Lionel Crawford in London, reported that immunoprecipitation of the large T (tumor) antigen encoded by the SV40 transforming gene also brought down a 53kd host protein. Daniel Linzer and Arnold Levine reported similar data and it became clear that T antigen blocks the natural function of p53 to regulate cell division and to direct cells to an apoptotic pathway. TSp53 became the “canonical” tumor suppressor that Lane dubbed the “guardian of the genome”. Mutations of the p53 gene in human cancers have a similar effect to its sequestration by T-antigen. Many other types of oncogenic DNA viruses encode proteins that block TSp53 function, such as E6 of HPV and the latent nuclear antigen of Kaposi’s sarcoma virus. Knocking out TSp53 function triggers the “S” phase of the cell division cycle which the viruses need to synthesize their own DNA.

Harnessing of Viruses by Humans

In this section, we cite examples of how humans have harnessed or attempted to harness viruses, not only for economic and medical benefits, but also for darker ends.

Commerce and Tulip Mania

Compared to centuries-old industries of fermentation that rely on bacteria and yeasts – think of wine, beer and bread – the exploitation of viruses for commercial purposes is still in its infancy. One exception was the unwitting use in the seventeenth century of plant viruses to develop varieties of tulips with different variegations in their flowers. The tulip mania in The Netherlands led to the sale of single tulip bulbs at prices up to 10-fold higher than the average annual earnings of farmers. In February 1637, the market suddenly collapsed, ruining many businessmen who had invested in tulip “futures”. The most treasured tulips were difficult to breed consistently because the pattern of the color “breaks” in the petals was erratic. We now know that the streaked appearance of the prized tulips is caused by the Potyvirus, Tulip Breaking Virus – discovered in 1928 by Dorothy Caley.

Vaccines

The development of vaccines as a means to prevent viral diseases is one of the best known and oldest examples of humans harnessing viruses. As in the cases of fermentation and horticulture mentioned above, the practice predates actual knowledge about the existence of the effector. The English physician Edward Jenner developed the first safe vaccine against smallpox, which was based on the fact that cowpox causes a mild lesion when introduced into the skin of uninfected persons, but cross-protects them against smallpox itself. It represented a major advance to the previous use of immunization with low doses of variola virus

(the smallpox agent) itself, which had a 2% risk of causing smallpox. Live, attenuated viruses such as Sabin polio vaccine, tend to be efficacious because, while the virus propagates to a lower level than wild-type virus, it is sufficient to elicit immunity without causing disease. Other virulent viruses can elicit protective immune responses after they have been chemically inactivated, e.g., the Salk polio vaccine. Influenza virus vaccines are typically made up of immunogenic components of disassembled viral antigens. Several of the current attempts to design a vaccine against SARS-CoV-2 are targeting the “S” spike glycoprotein.

Despite vaccination having led to immense advances in public health to protect against many infectious diseases, there has been a rise in recent years of antagonism to childhood immunizations such as the combined measles, mumps and rubella vaccine. The fear of parents has been fueled by fake news of vaccine dangers and false associations of vaccines with other diseases. Sadly, this situation has resulted in unnecessary outbreaks of measles and mumps in developed countries.

Phage therapy

When d’Herelle first observed the lytic effect of bacteriophages on bacteria in 1916, he immediately envisaged their use in controlling bacterial diseases, describing his finding as the ‘true microbe of immunity.’ He believed that phages were responsible for natural resistance of populations to diseases such as dysentery and cholera in regions of the world where the diseases were endemic, maintaining an interest throughout his career. Phage therapy attracted wide attention at first, even spurring the imagination of the American novelist Sinclair Lewis who included phages in his Pulitzer Prize-winning novel, *Arrowsmith*. Phage therapy all but disappeared from the West after WWII, owing to the greater efficacy and reliability of antibiotics, but in the pre-antibiotic world in 1930s and early 1940s, various bacteriophage products were commercially available in many countries. It was promoted in the Soviet Union, and continues at the Eliava Institute of Bacteriophage, Microbiology & Virology which d’Herelle helped to found in Tbilisi, Georgia. Recently, the emergence of antibiotic-resistant bacterial pathogens has stimulated a revival of interest in phage therapy, although bacteria can become resistant to phage as well as to antibiotics.

Gene therapy and cancer therapy

Ever since the advent of recombinant DNA technology, medical researchers have been using viruses as vectors or vehicles for delivering specific genes to target host cells as a possible means of therapy for single gene inherited disorders, such as cystic fibrosis, as well as for treating cancer. Vectors such as vaccinia virus and retroviruses may also be designed to carry genes encoding antigens of different viruses or other pathogens for immunization. Recombinant viruses, such as adeno-associated virus, can express high levels of antibody as a means of delivering passive immunotherapy. Lytic viruses can be modified to replicate only in proliferating cells in order to treat cancer. All these approaches are recent developments and are likely to have greater impact on human health in the future.

Bioweapons

The use of viruses for biological warfare is poorly documented. Smallpox may have been spread deliberately by Francisco Pizzaro during the conquest of the Inca empire because its inadvertent effect on the Aztecs 11 years earlier had been noted. One record of the use of viruses in conflict occurred during the Franco-British war for control of North America. Different Native American communities sided with the French or the English. The Redcoat Colonel Henry Bouquet sent his commander, General Lord Jeffrey Amherst, a request “to inoculate the Indians” by sending smallpox-impregnated blankets to them who, under the leadership of Chief Pontiac, were besieging Fort Pitt (Pittsburgh). In a postscript to his reply on 16 July 1763, Amherst approved this request and added that Bouquet should ‘try every method that can serve to extirpate this execrable race’.

We look upon multi-ethnic USA differently 250 years later! In 2016, student activists at Amherst College demanded the deletion of Jeffrey Amherst’s name. The Trustees of Amherst College dismissed the issue of the College’s name by stating that the College is named after the town and not the general. They did, however, remove the College’s “Lord Jeff” mascot and change the name of the “Lord Jeff Inn” on campus.

In the twentieth century, most of the potential germ warfare agents were bacterial such as anthrax and tularemia, but it appears that the Nazi regime also tested highly pathogenic viruses on concentration camp victims. The Friedrich Löffler Institute on Riems island in the Baltic Sea, founded in 1910 by the discoverer of foot and mouth disease virus, became a testing ground for bioweapons during WWII, but is now devoted to vaccine research and development. In the Soviet Union, there was a bioweapons establishment near Novosibirsk in Siberia. Vozrozhdeniya Island, in what used to be the Aral Sea, was a testing ground for bioweapons until the collapse of the Soviet Union and it remains contaminated.

Following the eradication of smallpox as a naturally occurring infection, there was debate whether to destroy the remaining stocks of the virus, officially stored in Russia (at Novosibirsk) and in the USA (at the Centers for Disease Control and Prevention – CDC – in Atlanta). In 1996, on the 200th anniversary of Jenner’s first vaccination of young James Phipps, the World Health Organization voted to destroy all official laboratory stocks of the smallpox virus, but this deliberate extinction of a species has yet to be carried out. The issue remains controversial among virologists, some of whom say that preservation is advisable for future work on vaccines or on any novel pox viruses that might emerge, while others argue that, with full genome sequence data of variola in the open domain, there is no need to preserve the virus itself.

It is not clear whether any terrorist organizations or ‘rogue’ nations possess dangerous viruses such as smallpox or Crimean-Congo Hemorrhagic Fever virus (a frequently fatal orthonairovirus), which is naturally transmitted by animal ticks but can also spread among humans via bodily fluids and aerosols. Unofficial stocks of smallpox virus might still exist, either hidden by those

with malicious intent, or which have simply been overlooked. An example of the latter was the discovery in 2016 of vials of variola virus in a freezer at the US National Institutes of Health in Bethesda, Maryland, which were subsequently shipped to the CDC.

Impact of Viruses on Society

It might be appropriate to call this section “the impact of viruses on *other* aspects of society”, because science is, after all, very much a human activity and thus part of society. Here, we address the impact of viruses beyond the laboratory. Undoubtedly the most recognizable impact of viruses is their ability to cause epidemic disease. While our primary focus here will be on human disease, we also touch on viral pathogens of livestock and crops, before ending with a brief look at the influence of viruses on other spheres of human activity, notably the arts and literature.

Impact on Human Disease

We know little of the precise times and origins of the plagues of old, but they seem to have appeared when dense populations developed on irrigated land. This seems evident from the cultural myths of those regions: the Nile delta, the Fertile Crescent, the Indus Valley and the area between the Yellow and Yangtze rivers. Yet based on both historical records and archeological evidence one can say that the humans have been subject to viral diseases for as long as we have existed.

The success of vaccines and antibiotics in the mid-twentieth century led to hopes that infectious diseases in general may become largely a phenomenon of the past, like smallpox. In their fine book *Natural History of Infectious Disease* (1972), McFarlane Burnet and David White commented: “The most likely forecast about the future of infectious disease is that it will be very dull. There may be some wholly unexpected emergence of a new and dangerous infectious disease, but nothing of the sort has marked the past fifty years”. A half century later, however, we can see that infections have been anything but dull. Ebola broke out in the Congo in 1976, AIDS began to take lives in the early 1980s and at the time of writing we are in the throes of the COVID-19 crisis which began in December 2019.

The origins and historical demographics of viral infections in humans

Some human viruses have always been with us whereas others have transferred from animal hosts. From the “germ’s eye view” it appears that it was the massive changes to human society in the wake of the prehistoric agricultural revolution some 10,000 years ago that provided the opportunity for so many new types of viruses to take up residence in humans. The successful colonization by viruses of foreign origin was a consequence, first of human dispersion out of Africa, second of domestication of livestock and most importantly, the development of large, densely populated communities.

There are many zoonotic viruses, e.g. rabies and H5N1 influenza, that have never become epidemic in humans. An estimated 60% of the 1400 species of infectious microbes known to be pathogenic in humans are transmitted by animals, for which the human usually represents a dead-end host. Viruses that do adapt to human-to-human spread, however, can become self-sustaining providing there is a human population of 250,000 or greater of naïve hosts to infect. Measles, according to recent phylogenetic molecular clock studies, is believed to have diverged from rinderpest of cattle approximately 2400 years ago, and the smallpox strain that was present until eradication, most likely arose in the early Christian era from the Bactrian camel, though burrowing rodents were the ultimate source. These viruses have diverged from their progenitors and only circulate in the human population.

Influenza viruses emerge and re-emerge from reservoirs in waterfowl. Having segmented genomes, they can re-assort with genes of existing strains circulating in humans and other mammals to form new epidemic variants. The “Spanish Flu” pandemic of 1918/1919 was an H1N1 strain that may have arisen in horses of the trenches in World War I. Many modern sources of zoonoses indicate a shift from an origin in livestock or in “companion animals” like dogs and rats, to viruses from exotic species. Deforestation, a taste for bushmeat and other environmental or behavioral factors have increased the opportunities for viruses to reach humans from bats, like Ebola, SARS and Nipah, often via a short-term intermediate host, and from simians, like Zika and other mosquito-borne viruses.

For populations in which epidemic viruses are already resident and widespread, most surviving adults have acquired what is called herd immunity and new infections typically occur in children. However, when the virus reaches a host population that has not previously had experience of that virus, it can infect children and adults alike. The globalization of maritime travel following the explorations of Christopher Columbus and Vasco da Gama at the end of the fifteenth century allowed smallpox, measles and other “Old World” viruses reach new human populations.

The impact on the societies previously unexposed to these viruses proved to be devastating. No other viral disease has affected as many people throughout history as smallpox. Its accumulated mortality was huge, and it has repeatedly ravaged different populations. The introduction of smallpox to the New World during the 1521 conquest of the Aztec empire by Hernán Cortes and his band of Conquistadors, is recounted in vivid detail by Bernal Diaz in his diary, *The Conquest of New Spain*. In the ensuing 100 years, the populous regions of North America from Guatemala to the Mississippi basin lost around 90% of its indigenous peoples from smallpox and measles. This population decline was significantly greater than that in Europe following the Black Death. While it took 200 years for Western Europe to regain its pre-1348 population level, the lot of the survivors improved. For peasants, it became a bull labor market and they fought for and won freedom from serfdom (hereditary indentured labor). The decimation of indigenous peoples in America by smallpox had a greater and more sinister consequence: the need for manpower in the New World plantations engendered the trans-Atlantic slave trade.

This pattern of devastation by viruses was repeated globally as further new worlds were contacted in South America, Australia and Oceania. It continues today when isolated Amazonian tribes are contacted by “civilization”. As observed by Charles Darwin in his *Notes of the Voyage of the Beagle* in 1838: ‘Wherever the European has trod, death seems to pursue the aboriginal ... Most of the diseases have been introduced by ships and what renders this fact remarkable is that there might be no appearance of the disease among the crew which conveyed this destructive importation.’

Viral epidemics in the past century

Perhaps our best weapon against viral infections in the past century and a half has been vaccination; it has effected the eradication of smallpox, and the control of many other viral diseases including rabies, influenza, yellow fever, polio myelitis, measles, mumps and rubella, and most recently the human papilloma viruses associated with cervical cancer.

But we haven't conquered all viruses by any means. Despite the development of vaccines against it, influenza virus continues to wreak havoc, killing an estimated extra 280,000 people as recently as the H1N1 pandemic in 2009. Since it first appeared four decades ago, HIV has accounted for some 39 million AIDS deaths, 66% of them in Africa. In addition, AIDS has had an enormous socio-political impact.

In the early phases of the epidemic in North America, HIV targeted marginalized social groups, notably male homosexuals and intravenous drug-users. On the one hand, this apparent predilection exacerbated the discrimination against homosexuals by fundamentalist religious groups and by political conservatives who opposed certain types of demographic surveys about sexual behavior, which was detrimental for learning about disease epidemiology. On the other hand, the AIDS epidemic mobilized the gay community, especially in the US, to social activism, resulting in widespread appeals and funding for research and public awareness about the disease. Meanwhile, the demographics of AIDS incidence in low income nations, especially Africa, also mobilized efforts to roll out anti-retroviral therapy across Africa, and by public health communities for better sex education and safer sexual practices.

Impact on human capital in the era of COVID-19

Plunged in the COVID-19 pandemic as we are, it is not yet possible to accurately estimate its mortality rate. SARS-CoV-2 has a high mortality rate in hospitalized cases of infection, whereas the mortality in the general population is likely to be much lower, once the prevalence of infection has been ascertained by serological studies. The SARS and MERS coronaviruses are more highly pathogenic than SARS-CoV-2, but fortunately could be contained. That makes them easier to hunt down and box in via contact tracing because, like smallpox virus, there is little onward transmission before symptoms appear.

Four other strains of human coronavirus are highly transmissible and represent around 20% of ‘common colds’. One can speculate whether they caused similar mortality to SARS-CoV-2 when first introduced to humankind. With COVID-19, elderly people are at most risk of severe disease and death, which contrasts with the 1918/19 ‘flu pandemic, when many old people got off “lightly”. The reason why the elderly were relatively protected in 1918/19 was possibly due to an immune memory of a previous outbreak of a related ‘flu virus sometime in the late nineteenth century.

A better social indicator of disease impact than mortality is the disability-adjusted life year (DALY) expressed as the number of years lost due to ill-health, disability or early death. Given that COVID-19 tends to be most severe in older people, if we were to measure DALYs, the cost to society of COVID-19 affecting human capital, the workforce and those still in formative years of education ought to be relatively slight compared to the Spanish ‘flu and HIV. These two 20th century pandemics took out mainly young adults, the very cohorts in whom society had invested maximum social capital.

SARS-CoV-19 infection, nonetheless, appears set to exceed the mortality of any other novel virus since HIV (~39 million over a “flattened” 40 years), and the Spanish ‘flu a century ago (over 50 million deaths within a mere 18 months). The main driver of the profound effects that we are currently witnessing on the global economy and our livelihoods lies in our attempts to ameliorate the spread COVID-19, for which most nations were ill-prepared. It appears that complex, inter-connected modern societies and economies are more fragile in the face of a novel pandemic than 100 year ago.

While we may marvel at the speed of the identification of the new coronavirus and the use of rapid early diagnostic tests by genome amplification, we are humbled by the fact that we still rely on centuries old means of trying to contain the pandemic. We are using quarantine methods (self-isolation) dating from Venice’s approach to the Black Death 670 years ago, and the social distancing imposed on lepers. The advice “wash your hands” is a legacy from Ignaz Semmelweis whose medical colleagues ignored him as they made their way from the morgue to the delivery room. We hope that a COVID-19 vaccine will soon be developed given the number of candidates under preclinical and clinical trial, but an efficacious and long-lasting one may take a little longer to achieve.

Impact of Viruses on Livestock and Crops

Textbooks of veterinary virology and plant virology are as weighty as those about human viruses, owing to the great variety of viruses that threaten animal and plant health. Our 120-year knowledge that foot and mouth disease is caused by a virus has not entirely prevented it, as evidenced by the 2001 outbreak in the UK that resulted in serious economic loss to farmers through obligatory culling of livestock. The epidemic was probably triggered by the illegal addition of kitchen food waste containing imported ham to pig swill, and it then spread rapidly by transport of cattle and sheep traded in markets. Probably the best recognized viral pathogens of animals are strains of influenza, with reservoirs in wild waterfowl but initiating epidemics in domestic birds, horses and pigs. Tick-borne African Swine Fever Virus, endemic in wart hogs and bush pigs, has spread in recent

decades far beyond East Africa and is currently a serious problem in China. The orbivirus causing bluetongue disease in ruminants is broadening its geographic range northwards from Africa to Europe with the spread of its midge vector due to global warming, as well as colonization of new midge species. Tilapia lake virus first emerged in 2014 and is affecting Tilapia pisciculture in South America, Africa and south-east Asia where the fish is an important source of protein in the human diet.

The greatest success story in veterinary virology was the eradication of rinderpest, a disease of cattle caused by a morbillivirus. Regular outbreaks of rinderpest previously had a profound impact on herding communities in East Africa. This disease, together with the trypanosome parasite causing sleeping sickness, rendered large swathes of Africa inhospitable for imported domestic cattle. After a \$5 billion campaign that began in 1995, the United Nations Food and Agricultural Organization declared the global disappearance of rinderpest in June 2011, the second virus after smallpox to be eradicated. In June 2019, the Pirbright Institute in the UK destroyed its repository of different rinderpest virus strains, having documented their genetic sequences.

The best studied viral pathogen of crops is undoubtedly TMV which played such an important role in virology discussed earlier. With hindsight, we know that tobacco itself is a scourge upon humankind, but through its introduction to the Old World in the sixteenth century Colombian Exchange, it became an important commodity. Cauliflower mosaic virus (no relation to TMV) is notable both as a pathogen of cruciferous plants and because it replicates via reverse transcriptase like retroviruses. One of the most important plant viruses that is currently affecting food security is African cassava mosaic virus, a member of the Geminivirus family.

Viruses in Art and Literature

As with almost anything that we humans have encountered, viruses have stirred our imaginations in different ways and have made their way into our creative pursuits. The functional beauty of virus particles has caught the attention of artists, designers and architects. Conversely, buildings have inspired virologists to deduce virus structures more precisely. In 1962, Donald Caspar and Aaron Klug proposed a model of icosahedral (20-sided) particles drawn from the architect-designer Buckminster Fuller's geodesic domes who himself became enchanted with this analogy. He had solved a means to erect stable 'spherical' buildings composed of triangulated, pentagonal and hexagonal sided domes and it became apparent that viruses had solved the problem before humans did. Viruses with small genomes require many copies of one or two proteins to form the capsid surrounding the RNA or DNA genome. Bacteriophage MS2 has this type of structure and so do human adenoviruses. The recombinant human papilloma virus vaccine is self-assembled from one viral protein, L1, to form empty (genome free) "virus like particles" that possess this structural integrity. Moreover, the particulate nature of the vaccine renders it highly immunogenic.

Epidemic disease in particular has been the inspiration and subject of many works of literature. One of the most enduring examples is in Thucydides's *History of the Peloponnesian War*, where he provided a first-hand account of the 430 BCE "Plague of Athens", which may have been a typhus or viral outbreak.

No other disease in the twentieth century has generated as much as the AIDS pandemic in so many different spheres of the literary, performing and visual arts: The plays *A Normal Heart* by Larry Kramer (1985) and *Angels in America* by Tony Kushner (1992), were both explicit in their criticism of the social and medical response to the plight of the gay community in the early years of the AIDS outbreak; Randy Shilts's *And the Band Played On* (1987) provided a chronicle of the new disease and the unfolding of scientific breakthroughs; Thom Gunn produced an anthology of poetry *The Man With the Night Sweats* (1992) while AIDS ravaged San Francisco; and Abraham Verghese provided a doctor's perspective of treating the disease in the deeply conservative rural Tennessee in his moving *My Own Country* (1994). AIDS also gave a new guise to Giacomo Puccini's *La Boheme* – itself based on tuberculosis – when Jonathan Larson's award-winning rock opera *Rent* hit Broadway in the mid-1990s. Last but not least, there is one of the largest and possibly longest-running piece of community folk art in the world: the NAMES Project Memorial Quilt, better known as the AIDS Quilt. Conceived in 1985 by the activist Cleve Jones to celebrate the lives of those lost due to AIDS, it is currently estimated to weigh about 54 tons, and from 2020 will be on permanent display in San Francisco where it originated.

We end with an allusion to two modern classics: Chinua Achebe's novel *Things fall apart* (1958) which describes the strain and collapse when a traditional West African society becomes 'infected' by a foreign culture of missionaries and colonial officers. Although not itself about viral epidemics, the title alludes to the famous lines in WB Yeats' poem *The Second Coming*, written in 1919 at the height of the Spanish 'flu pandemic:

Things fall apart; the center cannot hold;

Mere anarchy is loosed upon the world,

The blood-dimmed tide is loosed, and everywhere

The ceremony of innocence is drowned.

EDITORS IN CHIEF

Dennis H. Bamford, PhD, is Professor Emeritus of Virology at the Faculty of Biological and Environmental Sciences, University of Helsinki, Finland. He obtained his PhD in 1980 from the Department of Genetics, University of Helsinki. During 1981–1982 he was an EMBO postdoctoral fellow at the Public Health Research Institute of the City of New York, United States, and during 1983–1992 he worked as a Senior Scientist at the Academy of Finland. In 1993 he was appointed Professor of General Microbiology at the University of Helsinki. He was awarded the esteemed Academy Professorship twice, in 2002–2007 and 2012–2016, and he also served twice as the Director of the Finnish Center of Excellence (in Structural Virology, 2000–2005, and in Virus Research, 2006–2011). Prof. Bamford has had continuous external research funding (e.g., from several European Union, Academy of Finland, TEKES and Jusélius Foundation funds, as well as the Human Frontier Science Program). He is an EMBO member and has held several positions of trust in scientific and administrative organizations.

Prof. Bamford has published approx. 400 articles in international peer-reviewed journals in virology, microbiology, biochemistry, and molecular biology (36 of them in high impact journals). About half of the primary articles have been published with international collaborators showing high international integration. He has also been invited to give 56 keynote and plenary presentations in major international meetings. Prof. Bamford has supervised over 35 Master's and

over 40 PhD theses. Seven of his graduate students or post docs have obtained a professorship and a similar number have a principal investigator status. Prof. Bamford has studied virus evolution from a structure-centered perspective, showing that seemingly unrelated viruses, such as bacteriophage PRD1 and human adenovirus have similar virion architecture. When the corona virion architecture was gradually revealed, it was observed that its structural elements were close to those seen in RNA bacteriophage phi6 so that phi6 has been actively used as surrogate for pathogenic viruses - quite a surprise!

Dr. Mark Zuckerman is Head of Virology, Consultant Medical Virologist, and Honorary Senior Lecturer at South London Specialist Virology Centre, King's College Hospital NHS Foundation Trust and King's College London Medical School, Department of Infectious Diseases, School of Immunology and Microbial Sciences in London, United Kingdom. His interests include the clinical interface between developing molecular diagnostic tests relevant to the local population of patients, respiratory virus infections, herpesvirus infections in immunocompromised patients and blood-borne virus transmission incidents in the healthcare setting. He has chaired the UK Clinical Virology Network, Royal College of Pathologists Virology Specialty Advisory Committee and Virology Examiners Panel and is a member of the Specialty Advisory Committee on Transfusion Transmitted Viruses. He is a co-author on four editions of the "Mims' Medical Microbiology" textbook, has written chapters in a number of other textbooks and has over 100 publications in international peer-reviewed journals and is an associate editor for two journals.

SECTION EDITORS

Claude Fauquet received his PhD in biochemistry from University Louis Pasteur in Strasbourg, France in 1974. Dr. Fauquet joined the Institut de Recherche pour le Développement (IRD) and worked there as a plant virologist for 28 years, and served in Ivory Coast, West Africa for 14 years. In 1991, he founded the International Laboratory for Tropical Agricultural Biotechnology (ILTAB) at The Scripps Research Institute, CA, United States. ILTAB was then hosted by the Donald Danforth Plant Science Center, St. Louis, MO, from 1999 to 2012. In 2003, he co-founded the Global Cassava Partnership for the 21st Century (GCP21), which he directed until 2019 and which goal is to improve the cassava crop worldwide.

Dr. Fauquet is an international leader in plant virology including taxonomy, epidemiology, molecular virology, and in gene-silencing as an antiviral strategy. He was Secretary of the International Committee on Taxonomy of Viruses (ICTV) for 18 years and the editor of several ICTV Reports including the VIIIth ICTV Report in 2005.

He has published more than 300 research papers in reviewed journals and books. He is a fellow of the American Association for the Advancement of Science, of the American Phytopathological Society and a member of the St. Louis Academy of Sciences. In 2007, Dr. Fauquet was knighted “Chevalier de l’Ordre des Palmes Académiques” by the French Minister of High Education and Research.

Dr. Michael Feiss is Professor Emeritus in the Department of Microbiology and Immunology of the Carver College of Medicine at the University of Iowa, IA, United States. Dr. Feiss received his PhD in Genetics at the University of Washington followed by a postdoctoral traineeship in the laboratory of Dr. Allan Campbell at Stanford. Dr. Feiss is a microbial geneticist who studies virus assembly with an emphasis on how a DNA virus, bacteriophage lambda, packages viral DNA into the empty prohead shell. The lab investigates how sites in the viral DNA orchestrate the initiation and termination of the DNA packaging process. This work includes comprehensive examination of the DNA recognition sites. A related interest is study of terminase, the viral DNA packaging enzyme, including the functional domains for protein–DNA and protein–protein interactions. A second focus has been the roles of the bacterial host’s IHF and DnaJ proteins in the lytic life cycle of the virus. More recent work has involved a genetic dissection of the role of terminase’s ATPase center that powers translocation of viral DNA into the prohead. This interest in the ATP hydrolysis-driven packaging motor involves a multidisciplinary collaboration examining the kinetics of DNA packaging during individual packaging events. Finally, recent studies have also looked at how the packaging process has diverged among several lambda-like phages, including phages 21, N15, and Gifsy-1.

Elizabeth E. Fry is a senior postdoctoral scientist in structural biology at the University of Oxford, Oxford, United Kingdom, where she received her DPhil. for studies relating to the structure determination of Foot-and-Mouth Disease Virus. Specializing in structural virology, Dr. Fry has studied many virus/viral protein structures but her primary focus is on picornavirus structure and function, in particular receptor interactions and virus uncoating. She is particularly interested in rationally designing virus-like-particles as next generation vaccines to reduce the inherent risks in handling live viruses.

Said A. Ghabrial[†] received his BSc in 1959 from Cairo University, Cairo, Egypt, and his PhD from Louisiana State University, Baton Rouge, LA, United States, in 1965. Dr. Ghabrial did postdoctoral research at the University of California, Davis, CA, United States, before returning to Cairo, where he served as a plant virologist in the Ministry of Agriculture. He returned to the United States in 1970 to do postdoctoral research at Purdue University, West Lafayette, IN. In 1972, he joined the Plant Pathology Department at the University of Kentucky, Lexington, KY, United States, where he rose to the rank of professor in 1986 and worked until 2013.

Dr. Ghabrial has served as an associate and senior editor of *Phytopathology*. He served on the editorial boards of the *Encyclopedia of Virology*, 3rd edition and *Encyclopedia of Plant Pathology*, and edited a thematic issue of *Advances in Virus Research* on "Mycoviruses". He was a member of the American Phytopathological Society (APS) and the American Society for Virology (ASV); in July 2002 he was elected as a Fellow of the American Phytopathological Society. He also acted as Chair of the ICTV Subcommittee on Fungal Viruses in 1987–1993 and 2011–2014.

His long professional career allowed him to make many scientific achievements in phytopathology and virology. Among them are molecular dissection of a legume-infecting RNA virus, bean pod mottle virus (BPMV), development of BPMV-based vectors, discovery of a transmissible debilitation disease of the phytopathogenic ascomycete, *Helminthosporium victoriae* (*Cochliobolus victoriae*), establishment of a viral etiology of the *H. victoriae* disease, and advancement of structural biology of diverse fungal viruses.

Eric Hunter, PhD, is Professor of Pathology and Laboratory Medicine at Emory University, Atlanta, GA, United States. He serves as Co-Director of the Emory Center for AIDS Research and is a Georgia Research Alliance Eminent Scholar.

Dr. Hunter's research focus has been the molecular virology and pathogenesis of retroviruses, including human immunodeficiency virus. He has made significant contributions to the understanding of the role of retroviral glycoprotein structural features during viral entry and providing unique insights into the assembly and replication of this virus family. In recent years the emphasis of his research has been on HIV transmission and pathogenesis, defining the extreme genetic bottleneck and selection of viruses with unique traits during HIV heterosexual transmission. He has described the selection of fitter viruses at the target mucosa, a gender difference in the extent of selection bias, and a role for genital inflammation in reducing selection. His research has defined the impact of HIV adaptation to the cellular immune response on immune recognition and control of HIV after

transmission, as well as on virus replicative fitness in vitro and in vivo. Recent work highlights the roles that virus replicative fitness and sex of the host play in defining disease progression in a newly infected individual. His bibliography includes over 300 peer-reviewed articles, reviews, and book chapters. He has also been the recipient of four NIH merit awards for his work on retrovirus and HIV molecular biology.

Dr. Hunter served as the Editor in Chief of the journal *AIDS Research and Human Retroviruses* for 10 years. He was Chair of the AIDS Vaccine Research Subcommittee which is charged with providing advice and consultation on AIDS vaccine research to the National Institute of Allergy and Infectious Diseases and continues to serve on editorial boards for several academic journals and on external advisory committees for several government, academic, and commercial institutions.

Ilkka Julkunen graduated as an MD/PhD in 1984 from the Department of Virology, University of Helsinki, Helsinki, Finland. He worked as a postdoctoral research fellow at Memorial Sloan-Kettering Cancer Center in New York, United States, in 1986–1989, followed by positions as a senior scientist, group leader and research professor at Finnish Institute for Health and Welfare in 1989–2013. In 2013 he became a Professor of Virology at the University of Turku, Turku, Finland. The research interests of Dr. Julkunen have concentrated on innate and adaptive humoral immunity in viral and microbial infections. He has studied intracellular signaling and RIG-I and TLR-mediated activation of interferon system in human macrophages and dendritic cells and stable cell lines in response to human and avian influenza, Sendai, Zika and coronavirus infections. In addition, he has analyzed the downregulation of innate immunity by viral regulatory proteins from influenza, HCV, flavi-, filo- and coronaviruses. He has expertise in vaccinology, biotechnology and development of methods to analyze antiviral immunity, he has also been actively involved in research training and collaborations with biotechnological industry.

[†]Deceased.

Peter Krell started his career in virology early as a summer high school student working for the Canadian Forestry Service studying the resistance of nuclear polyhedrosis viruses (now called baculoviruses) to environmental exposure with Dr. Fred T. Bird at the Insect Pathology Research Institute in Sault Ste. Marie, ON, Canada. He received his BSc and MSc in biology from Carleton University studying the iridovirus *Tipula Iridescent Virus* with Dr Peter Lee, in Ottawa, the Canadian capital. For his PhD he headed east to Dalhousie University in Halifax, Nova Scotia on the Atlantic coast. In addition to enjoying the salt sea air, fresh cod, lobster and mussels, he studied the molecular biology of polydnaviruses under the guidance of Dr Don Stoltz. Heading south to Texas A&M University in College Station, TX, United States, as a Postdoctoral Fellow he worked with Dr. Max Summer, of baculovirus fame, and Dr. Brad Vinson continuing to study polydnaviruses, but also became steeped in the early days of molecular baculovirology. He then accepted a faculty position in the Department of Microbiology and Immunology at the University of Guelph in Guelph, ON, Canada. There he switched to baculovirus research, which was more tractable, due in part to available cell cultures and focused on viral DNA replication and functional genomics,

particularly on chitinase, cathepsin and ME53. In collaboration with Dr. Eva Nagy he studied molecular biology of different animal viruses, notably Fowl Avian adenoviruses and their development as vaccine vectors, but also on the birnavirus infectious pancreatic necrosis virus, the coronavirus porcine endemic diarrhea virus, fowlpox virus and the paramyxovirus Newcastle disease virus. He has been involved extensively with virus taxonomy, being active in the International Committee on Taxonomy of Viruses (ICTV) as member of the *Polydnaviridae* and *Baculoviridae* study groups, national representative of Canada on the ICTV, member of the Executive Committee for the ICTV and Chair of the ICTV Invertebrate Virus Subcommittee. In terms of governance, Peter Krell was President of the Canadian Society of Microbiology, Secretary and later President of the Society for Invertebrate Pathology, as well as being on the Editorial Boards of the *Canadian Journal of Microbiology* and the *ASM Journal of Virology*. While at the University of Guelph, he rose through the ranks to Professor and is currently University Professor Emeritus.

Mart Krupovic is the Head of the Archaeal Virology Unit in the Department of Microbiology at the Institut Pasteur of Paris, France. He received his MSc in Biochemistry in 2005 from the Vilnius University, Vilnius, Lithuania and PhD in 2010 in general microbiology from the University of Helsinki, Helsinki, Finland. His current research focuses on the diversity, origin, and evolution of viruses, as well as molecular mechanisms of virus–host interactions in archaea. He has published over 170 journal articles and serves as an editor or on the editorial boards of *Biology Direct*, *Research in Microbiology*, *Scientific Reports*, *Virology*, and *Virus Evolution*. He is also a member of the Executive Committee of the International Committee on Taxonomy of Viruses (ICTV) and chairs the Archaeal Viruses Subcommittee of the ICTV.

Maija Lappalainen, MD, PhD, Associate Professor of Clinical Microbiology, is the Head of Clinical Microbiology in the HUS Diagnostic Center, HUSLAB, University of Helsinki and Helsinki University Hospital, Helsinki, Finland. In her thesis during the years 1987–1992 she studied the incidence and diagnostics of congenital toxoplasmosis. After PhD, her research interest has been in diagnostic clinical virology, viral hepatitis, respiratory infections, viral infections in the immunocompromised patients and viral infections during pregnancy.

Hubert G.M. Niesters (1958) studied biology and chemistry in Nijmegen, the Netherlands. After obtaining his PhD in Utrecht (Prof. dr. M. Horzinek and Prof. dr. B. van der Zeijst, 1987) on the molecular epidemiology of infectious bronchitis virus, he worked as a post-doctoral fellow with Prof. dr. Jim Strauss at the California Institute of Technology (Pasadena, United States) on the replication of Alphaviruses. He received a Niels Stensen fellowship (The Netherlands) and an E.S. Gosney fellowship (Caltech) during this period.

After returning to the Netherlands (1989), he became a research associate in medical microbiology at the Diagnostic Medical Center (Delft) but moved back to clinical virology as a senior research associate in 1991 at the Erasmus University Medical Center Rotterdam (Head Prof. dr. Ab Osterhaus). From 1993 to 2007, he was responsible for the molecular diagnostics unit. During this period, he was involved in the discovery and characterization of several new viruses and variants. In 2007, he became full professor and director of the Laboratory of Clinical Virology within the Department of Medical Microbiology at the University Medical Center Groningen and University of Groningen.

He has been actively involved in the implementation and development of new technologies like real-time amplification and automation within clinical virology. He has been focusing on molecular diagnostics and its use and the clinical value in a transplant setting, as well as in monitoring treatment of hepatitis viruses. Recently, his interest focuses on rapid regional epidemiology, automation including MiddleWare solutions for molecular diagnostics, as well as the cost-benefit of rapid point-of-impact molecular testing. Special interest is focused on raising awareness for the detection of enteroviruses (enterovirus D68) and its relationship with acute flaccid myelitis (AFM).

Since 2017, he is the Chair of the executive board of QCMD (Quality Control of Molecular Diagnostics, Glasgow). He is an auditor and team leader for the Dutch Council of Accreditation and Co-Editor in Chief of the *Journal of Clinical Virology*. He is an (co)-author of more than 250 peer-reviewed papers, chapters and reviews including emerging viruses, such as enterovirus D68 and hepatitis E virus (H-index 80).

For his entire work, he received in 2016 the “Ed Nowakowski Senior Memorial Clinical Virology Award” from the Pan American Society for Clinical Virology.

Massimo Palmarini is the Director of the MRC-University of Glasgow Centre for Virus Research and Chair of Virology at the University of Glasgow, Glasgow, United Kingdom. A veterinarian by training, his research programs focus on the biology, evolution and pathogenesis of arboviruses and the mechanisms of virus cross-species transmission. His work is funded by the MRC and the Wellcome Trust. Massimo Palmarini has been elected Fellow of the Academy of Medical Sciences, of the Royal Society of Edinburgh and of the Royal Society of Biology and he was a Wolfson-Royal Society Research Merit Awardee. He is a Wellcome Trust Investigator.

David Prangishvili, PhD, Honorary Professor at the Institut Pasteur, Paris, France, and Professor at Tbilisi State University, Tbilisi, Georgia, is one of the pioneers in studies on the biology of Archaea and their viruses. His scientific career spans ex-USSR (Institute of Molecular Biology, Moscow; 1970–1976), Georgia (Georgian National Academy of Sciences, Tbilisi; 1976–1991), Germany (Max-Planck Institute for Biochemistry, Munich; University of Regensburg; 1991–2004) and France (Institut Pasteur, Paris, 2004–2020). In the research groups headed by him, several dozens of new species and eight new families of archaeal viruses have been discovered and characterized, which display remarkable diversity of unique morphotypes and exceptional genome contents. The results of his research contribute to the knowledge on viral diversity on our planet and change the field of prokaryotic virology, leading to the notion that viruses of

hyperthermophilic Archaea form a particular group in the viral world, distinctive from viruses of Bacteria and Eukarya, and to the recognition of the virosphere of Archaea as one of the distinct features of this Domain of Life. David Prangishvili is a member of the Academia Europaea, the European Academy of Microbiology, and the Georgian National Academy of Sciences.

David I. Stuart is MRC Professor of Structural Biology in the Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, Life Science Director at Diamond Light Source and Director of Instruct-ERIC (pan-European organisation providing shared access to infrastructure and methods for structural biology). He has diverse interests in structural virology from picornaviruses, double-stranded RNA viruses and enveloped RNA viruses. His drive to develop structural techniques led to the determination of the structure of Bluetongue virus (1995) and then the first membrane containing virus, PRD1. More recently, he has been at the fore-front of bringing Cryo-EM technology to bear on virus structure determination and its future role in visualizing virus function in cellulose. In addition to basic science he has a strong commitment to structural vaccinology and the development of antiviral drugs.

Dr. Nobuhiro Suzuki, PhD, received his MSc (1985) in phytopathology and PhD (1989) in virology from Tohoku University in Sendai, Japan. Dr. Suzuki currently serves as a full Professor of the Institute of Plant Stress and Resources, formerly Institute of Plant Sciences and Bioresources at Okayama University and as an Editor of *Virus Research*, *Frontiers in Virology*, *Journal of General Plant Pathology*, *Virology Journal*, and *Biology*. He has also been Guest Editor to *PLoS Pathogens*, *PNAS*, and *mBio*, and an Editorial Board member of *Virology* and *Journal of Virology*.

Suzuki Laboratory focuses on characterization of diverse viruses infecting phytopathogenic fungi and exploration of their interplays. Recent achievements include the discovery of a neo-virus lifestyle exhibited by a (+)ssRNA virus and an unrelated dsRNA virus in a plant pathogenic fungus and of multilayer antiviral defense in fungi involving Dicer. Prior to coming to Kurashiki, Okayama Prefecture, he was a visiting fellow of the Center for Agricultural Biotechnology at the

University of Maryland Biotechnology Institute (UMBI), College Park, MA, United States, for 4 years (1997–2001) to study molecular biology of hypoviruses in the laboratory of Professor Donald L. Nuss. Before visiting UMBI, he served as an assistant professor and a lecturer of the Biotechnology Institute at the Akita Prefectural College of Agriculture, Japan, for 11 years (1988–1998) where he was engaged in a project on molecular characterization of rice dwarf phytoecovirus, a member of the family *Reoviridae*. He received awards from the Japanese Phytopathological Society of Japan and Japanese Society for Virology for his outstanding achievements in plant and fungal virology.

FOREWORD

I am delighted to write the foreword to this wonderful Fourth Edition of the *Encyclopedia of Virology*. The Third Edition was published in 2008, how the world has changed in the intervening years. The release of the updated fourth edition could not be more timely or more prescient. It is superb and a huge tribute to the authors, Elsevier the publisher, and to the brilliant editors, Dennis Bamford and Mark Zuckerman.

SARS-CoV-2 has dominated the world since it emerged in 2019 and affected every continent and every aspect of life. A reminder, if it were needed, of the impact of infectious diseases, the importance of virology and the vulnerability and interconnectivity of our world.

There is no doubt that with rapidly changing ecology, urbanization, climate change, increased travel, and fragile public health systems, epidemics and pandemics will become more frequent, more complex and harder to prevent and contain. Most of these epidemics will be caused by viruses, those we know about and maybe able to predict and some we do not know of that will emerge from animals, plants or the environment. Our changing climate will change the epidemiology of viruses, their vectors and the infections they cause, hence the critical importance of this totally revised Fourth Edition of the *Encyclopedia of Virology* which brings together research and an understanding of viruses in animals, plants, bacteria and fungi, the environment, and among humans. Never has a holistic, one-health understanding been more important.

That starts with an understanding of the fundamentals of virology, a field of science that has been transformed in the years since the Third Edition. An understanding transformed by embracing traditional fields of molecular and structural biology, genomics, and influenced by immunology, genetics, pharmacology and increasingly by epidemiology and mathematics. Events of 2020 and 2021 also show why it is so important to integrate within traditional virology an understanding of the animal and human health and behavior, of climate change and its impact on the ecology of viruses, plant sciences and vectors. And why we must understand the viruses we think we know well, and those viruses less extensively studied. Research is critical to this, research that pushes the boundaries of what we know, has the humility to seek answers to things we do not understand and shares that knowledge with the widest possible community. That research will be most exciting at the interface between disciplines, most impactful when dynamic, open, inclusive, global, and collaborative.

This is what the Fourth Edition of the *Encyclopedia of Virology*, the largest reference source of research in virology sets out to achieve. It is a wonderful contribution to a critical field of knowledge. It contains new chapters, every chapter revised and updated by a dedicated global community who have come together to provide what is a brilliant and inspiring reference. It is an honor to contribute in a very small way to the timely release of the Fourth Edition of the *Encyclopedia of Virology*.

Jeremy Farrar

PREFACE

The fourth edition of the Encyclopedia of Virology is encyclopedic, but we wanted to move away from an alphabetical list, apart from where it was more logical, to a vision that encompassed a different structure. Articles describing novel trends as well as original discoveries in specific subfields of virology have been distributed into a set of five volumes, namely Fundamentals of Virology, Human and Animal Viruses, Plant Viruses, Bacterial, Archaeal, Fungal, Algal and Invertebrate Viruses, and Diagnosis, Treatment and Prevention of Virus Infections.

We had hoped that the new edition would 'go viral' but it was ironic that the time to publication 12 years after the previous edition had been made a bit longer due to a virus infection. The world encountered a devastating global pandemic, COVID-19, caused by a new type of a coronavirus, SARS-CoV-2. Scientists in many disciplines all over the world started immediate efforts to discover solutions as to how to mitigate and stop the spread of the pandemic. Virology moved from being a highly specialized subject to one in which everyone became a virologist, proving just how significant the different aspects of virology are in terms of understanding the nature of viral infection. Since the previous edition, the growth in the field of general virology has been enormous, including huge advances in basic science, identification of novel viruses, diagnostic methods, treatment and prevention. Taking this into account, the introduction of the articles within the Encyclopedia are very timely and crucial for providing a wealth of knowledge of the latest findings in the field of virology to a vast range of people, whether school students, undergraduates, postgraduates, teachers, scientists, researchers, journalists and others interested in infections and the conflict between the host and the pathogen.

Pandemic viruses have become a serious public concern in the changing world. We can ask ourselves whether we have reached the point in which nature can no longer cope with the consequences of increased population density and human activities that are harmful to the environment. Although several pandemics have threatened mankind before, this COVID-19 pandemic has highlighted the massive adverse economic consequences towards the wellbeing of society and the importance of research in virology.

We aimed to produce a Major Reference Work that differs in approach to others and binds all the virology disciplines together. Chapters have been included on origin, evolution and emergence of viruses, environmental virology and ecology, epidemiology, techniques for studying viruses, viral life cycles, structure, entry, genome and replication, assembly and packaging and taxonomy and viral–host interactions. Information has been included on all known species of viruses infecting bacteria, fungi, plants, vertebrates and invertebrates. Additional topics include antiviral classification and examples of their use in management of infection, diagnostic assays and vaccines, as well as the economic importance of viral diseases of crops and their control.

This edition used viral classification according to the 9th Report of the International Committee on Taxonomy of Viruses published in 2012. Updating it to the 10th Report in 2020 was affected by the pandemic and can be found online at <http://ictv.global/report/>.

We wish to acknowledge the hard work, interest, flexibility and patience, during such difficult times both socially and professionally, of everybody involved in the process of writing this edition of the Encyclopedia of Virology, especially Katarzyna Miklaszewska, Priscilla Braglia, Sam Crowe and colleagues at Elsevier. We sincerely thank all the authors and section editors for their excellent contributions to this edition.

Book Cover Image: Viruses are obligate parasites and all cells have their own viruses increasing the total number of viruses to the estimated astronomical number of 10^{31} that extends the number of stars in the universe. The viral string illustrates how pandemic viruses surround the globe. The original picture was created by Dr. Nina Atanasova (Finnish Meteorological Institute and University of Helsinki) and amended by Matthew Limbert at Elsevier.

*Dennis H. Bamford
Mark Zuckerman*

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged thematically as a series of entries within subjects/sections, apart from volume 2 where there it was more logical to have articles arranged alphabetically.

There are three features to help you easily find the topic you are interested in: a thematic contents list, a full subject index, and contributors.

1. Thematic contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia.
2. Index: The index appears at the end of volume 5 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
3. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

Julius Kühn Institute, Quedlinburg, Germany

Sheli R. Radoshitzky
United States Army Medical Research Institute of Infectious Diseases, Frederick, MD, United States

Saleem U. Rahman
National Institute for Biotechnology and Genetic Engineering, Faisalabad, Pakistan

Mbolarinosy Rakotomalala
FOFIFA, Antananarivo, Madagascar

Norma Rallon
Institute of Health Research-Jiménez Díaz Foundation, Autonomous University of Madrid and Rey Juan Carlos University Hospital, Móstoles, Spain

Robert P. Rambo
Diamond Light Source, Didcot, United Kingdom

Bertha Cecilia Ramirez
The Institute for Integrative Biology of the Cell, The French Alternative Energies and Atomic Energy Commission, French National Center for Scientific Research, University of Paris-Sud, University of Paris-Saclay, Gif-sur-Yvette, France

María D. Ramos-Barbero
University of Alicante, Alicante, Spain

Chris M. Rands
University of Geneva Medical School and Swiss Institute of Bioinformatics, Geneva, Switzerland

Venigalla B. Rao
The Catholic University of America, Washington, DC, United States

Janne J. Ravantti
University of Helsinki, Helsinki, Finland

Mandy Ravensbergen
Wageningen University and Research, Wageningen, The Netherlands

Georget Y. Reaiche-Miller
The University of Adelaide, Adelaide, SA, Australia

D.V.R. Reddy
International Crops Research Institute for the Semi-Arid Tropics, Hyderabad, India

Vishwanatha R.A.P. Reddy
The Pirbright Institute, Pirbright, United Kingdom

Juan Reguera
Aix-Marseille University, French National Center for Scientific Research, Marseille, France and French National Institute of Health and Medical Research, Marseille, France

William K. Reisen
University of California, Davis, CA, United States

Jingshan Ren
University of Oxford, Oxford, United Kingdom

Renato O. Resende
University of Brasilia, Brasilia, Brazil

Peter A. Revill
The Peter Doherty Institute of Infection and Immunity, Royal Melbourne Hospital, Melbourne, VIC, Australia

Félix A. Rey
Institut Pasteur, Paris, France

Lara Rheinemann
University of Utah, Salt Lake City, UT, United States

Simone G. Ribeiro
Embrapa Genetic Resources and Biotechnology, Brasília, Brazil

Daniel Rigling
Swiss Federal Institute for Forest, Snow and Landscape Research (WSL), Birmensdorf, Switzerland

Cristina Risco
Cell Structure Laboratory, National Center for Biotechnology – Spanish National Research Council (CNB-CSIC), Madrid, Spain

Efraín E. Rivera-Serrano

Lineberger Comprehensive Cancer Center, The University of North Carolina at Chapel Hill, NC, United States and Department of Microbiology and Immunology, The University of North Carolina at Chapel Hill, NC, United States

Cécile Robin

INRAE – French National Research Institute for Agriculture, Food and Environment, UMR BIOGECO, Cestas, France

Rodrigo A.L. Rodrigues

Federal University of Minas Gerais, Belo Horizonte, Brazil

Elina Roine

University of Helsinki, Helsinki, Finland

Maria R. Rojas

University of California, Davis, CA, United States

Marilyn J. Roossinck

Pennsylvania State University, State College, PA, United States

Vera I.D. Ros

Wageningen University and Research, Wageningen, The Netherlands

Cristina Rosa

Pennsylvania State University, University Park, PA, United States

Hanna Rose

Leibniz University Hannover, Hannover, Germany

David A. Rosenbaum

University of Florida, Gainesville, FL, United States

Shannan L. Rossi

The University of Texas Medical Branch, Galveston, TX, United States

Michael G. Rossmann[†]

Purdue University, West Lafayette, IN, United States

L. Roux

University of Geneva Medical School, Geneva, Switzerland

Simon Roux

US Department of Energy Joint Genome Institute, Walnut Creek, CA, United States

J. Rovnak

Colorado State University, Fort Collins, CO, United States

David J. Rowlands

University of Leeds, Leeds, United Kingdom

Polly Roy

Department of Pathogen Infection, Faculty of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, United Kingdom and University of Reading, Reading, United Kingdom

Aaron P. Roznowski

The University of Texas at Austin, Austin, TX, United States and University of Arizona, Tucson, AZ, United States

Luisa Rubino

Institute for Sustainable Plant Protection, National Research Council, Bari, Italy

Olli Ruuskanen

Turku University Hospital, Turku, Finland

Eugene V. Ryabov

USDA, Agricultural Research Service, Beltsville, MD, United States

Martin D. Ryan

University of St. Andrews, St. Andrews, United Kingdom

Ki H. Ryu

Seoul Women's University, Seoul, South Korea

Hanns-Joachim Rziha

Eberhard Karls University of Tübingen, Tübingen, Germany

Sead Sabanadzovic

Mississippi State University, Starkville, MS, United States

Roghayeh Safari

Cellular and Molecular Epigenetics (GIGA), Liège, Belgium and Molecular Biology (TERRA), Gembloux, Belgium

Azeez Sait Sahul Hameed

C. Abdul Hakeem College, Melvisharam, India

Nicole Samies

University of Alabama at Birmingham, Birmingham, AL, United States

Carmen San Martín

National Center for Biotechnology, Spanish National Research Council, Madrid, Spain

Ruth-Anne Sandaa

Department of Biological Sciences, University of Bergen, Bergen, Norway

Hélène Sanfaçon

Agriculture and Agri-Food Canada, Summerland, BC, Canada

[†]Deceased.

List of Contributors	xxi

VOLUME 1

The Virus as a Concept – Fundamentals of Virology

A Brief History of Virology <i>David J Rowlands</i>	3
The Origin of Viruses <i>Patrick Forterre and Morgan Gaïa</i>	14
The Virocell Concept <i>Patrick Forterre</i>	23
Virus Taxonomy <i>Jens H Kuhn</i>	28
The Greater Virus World and Its Evolution <i>Eugene V Koonin and Valerian V Dolja</i>	38
The Virus Species Concept <i>Peter Simmonds</i>	47
Genetic Diversity and Evolution of Viral Populations <i>Rafael Sanjuán and Pilar Domingo-Calap</i>	53
Mechanisms of RNA Virus Evolution <i>Lisa M Bono and Siobain Duffy</i>	62
Mechanisms of DNA Virus Evolution <i>Moriah L Szpara and Koenraad Van Doorslaer</i>	71
Paleovirology <i>Clément Gilbert</i>	79
Evolution Steered by Structure <i>Nicola GA Abrescia</i>	87

Pairwise Sequence Comparison in Virology <i>Tao Zhang, Zheng Gong, Tongkun Guo, Zhuang Xiong, and Yiming Bao</i>	100
Computational Analysis of Recombination in Viral Nucleotide Sequences <i>Miguel Arenas</i>	108
Phylogeny of Viruses <i>Alexander E Gorbalenya and Chris Lauber</i>	116
Virus Bioinformatics <i>Nikolaos Pappas, Simon Roux, Martin Hölzer, Kevin Lamkiewicz, Florian Mock, Manja Marz, and Bas E Dutilh</i>	124
Metagenomics in Virology <i>Simon Roux, Jelle Matthijnsens, and Bas E Dutilh</i>	133
Database and Analytical Resources for Viral Research Community <i>Sujal Phadke, Saichetana Macherla, and Richard H Scheuermann</i>	141
Classification of the Viral World Based on Atomic Level Structures <i>Janne J Ravantti and Nicola GA Abrescia</i>	153
Isolating, Culturing, and Purifying Viruses With a Focus on Bacterial and Archaeal Viruses <i>Katri Eskelin and Hanna M Oksanen</i>	162
High Throughput Sequencing and Virology <i>Graham L Freimanis and Nick J Knowles</i>	175
Single-Virus Genomics: Studying Uncultured Viruses, One at a Time <i>Manuel Martinez-Garcia, Francisco Martinez-Hernandez, and Joaquín Martínez Martínez</i>	184
Biophysical Characterizations in the Solution State <i>Robert P Rambo and Katsuaki Inoue</i>	191
Virus Crystallography <i>Jonathan M Grimes</i>	199
Advanced Light and Correlative Microscopy in Virology <i>Sergi Padilla-Parra, Charles A Coomer, and Irene Carlon-Andres</i>	208
Atomic Force Microscopy (AFM) Investigation of Viruses <i>Alexander McPherson</i>	218
Cryo-Electron Microscopy (CEM) Structures of Viruses <i>David Chmielewski and Wah Chiu</i>	233
Analysis of Viruses in the Cellular Context by Electron Tomography <i>Peijun Zhang and Luiza Mendonça</i>	242
Mathematical Modeling of Virus Architecture <i>Reidun Twarock</i>	248
Principles of Virus Structure <i>Madhumati Sevvana, Thomas Klose, and Michael G Rossmann[†]</i>	257
Structures of Small Icosahedral Viruses <i>Elizabeth E Fry, Jingshan Ren, and Claudine Porta</i>	278
Structural Principles of the Flavivirus Particle Organization and of Its Conformational Changes <i>Stéphane Duquerroy, Arvind Sharma, and Félix A Rey</i>	290
Reoviruses (Reoviridae) and Their Structural Relatives <i>Liya Hu, Mary K Estes, and B V Venkataram Prasad</i>	303

[†]Deceased.

Structures of Tailed Phages and Herpesviruses (<i>Herpesviridae</i>) <i>Montserrat Fàbrega-Ferrer and Miquel Coll</i>	318
Adenoviruses (<i>Adenoviridae</i>) and Their Structural Relatives <i>Gabriela N Condezo, Natalia Martín-González, Marta Pérez-Illana, Mercedes Hernando-Pérez, José Gallardo, and Carmen San Martín</i>	329
Negative Single-Stranded RNA Viruses (<i>Mononegavirales</i>): A Structural View <i>Juan Reguera</i>	345
Structure of Retrovirus Particles (<i>Retroviridae</i>) <i>David K Stammers and Jingshan Ren</i>	352
Structure of Helical Viruses <i>C Martin Lawrence</i>	362
Giant Viruses and Their Virophage Parasites <i>Rodrigo AL Rodrigues, Ana CdSP Andrade, Grazielle P Oliveira, and Jônatas S Abrahão</i>	372
Viral Replication Cycle <i>AJ Cann</i>	382
Viral Receptors <i>José M Casasnovas and Thilo Stehle</i>	388
Bacterial and Archeal Virus Entry <i>Minna M Poranen and Aušra Domanska</i>	402
Nonenveloped Eukaryotic Virus Entry <i>Ian M Jones and Polly Roy</i>	409
Enveloped Virus Membrane Fusion <i>Aurélien A Albertini and Yves Gaudin</i>	417
Genome Replication of Bacterial and Archaeal Viruses <i>Česlovas Venclovas</i>	429
Viral Transcription <i>David LV Bauer and Ervin Fodor</i>	439
Translation of Viral Proteins <i>Martin D Ryan and Garry A Luke</i>	444
Recombination <i>Jozef J Bujarski</i>	460
Assembly of Viruses: Enveloped Particles <i>CK Navaratnarajah, R Warriar, and RJ Kuhn</i>	468
Assembly of Viruses: Nonenveloped Particles <i>M Luo</i>	475
Virion Assembly: From Small Picornaviruses (<i>Picornaviridae</i>) to Large Herpesviruses (<i>Herpesviridae</i>) <i>Ling Zhu, Nan Wang, and Xiangxi Wang</i>	480
Genome Packaging <i>Richard J Bingham, Reidun Twarock, Carlos P Mata, and Peter G Stockley</i>	488
Virus Factories <i>Isabel Fernández de Castro, Raquel Tenorio, and Cristina Risco</i>	495
Release of Phages From Prokaryotic Cells <i>Jesse Cahill and Ry Young</i>	501
Virus Budding <i>Lara Rheinemann and Wesley I Sundquist</i>	519

Vesicle-Mediated Transcytosis and Export of Viruses <i>Efraín E Rivera-Serrano and Stanley M Lemon</i>	529
Vector Transmission of Animal Viruses <i>Houssam Attoui, Fauziah Mohd Jaafar, Rennos Fragkoudis, and Peter PC Mertens</i>	542
The Human Virome <i>Alexia Bordigoni, Sébastien Halary, and Christelle Desnues</i>	552
Epidemiology of Human and Animal Viral Diseases <i>Michael Edelstein</i>	559
Zoonosis, Emerging and Re-Emerging Viral Diseases <i>Janet M Daly</i>	569
Antiviral Innate Immunity: Introduction <i>Friedemann Weber</i>	577
Humoral and T Cell-Mediated Immunity to Viruses <i>Ane Ogbe and Lucy Dorrell</i>	584
Antigenicity and Antigenic Variation <i>Kuan-Ying A Huang, Xiaorui Chen, Che Ma, Dayna Cheng, Jen-Ren Wang, and Wan-Chun Lai</i>	597
Antigen Presentation <i>Andrew J McMichael</i>	601
Defense Against Viruses and Other Genetic Parasites in Prokaryotes <i>Kira S Makarova, Yuri I Wolf, and Eugene V Koonin</i>	606
Defective-Interfering Viruses <i>L Roux</i>	617
Ecology and Global Impacts of Viruses <i>Joanne B Emerson</i>	621
The Role of Retroviruses in Cellular Evolution <i>Andrea Kirmaier and Welkin E Johnson</i>	627
The Role of Bacteriophages in Bacterial Evolution <i>Chris M Rands and Harald Brüssow</i>	633
Viruses and Their Potential for Bioterrorism <i>Dana L Vanlandingham and Stephen Higgs</i>	644
The Use of Viral Promoters in Expression Vectors <i>Ian M Jones</i>	652
Oncolytic Viruses <i>Laura Burga and Mihnea Bostina</i>	658
Biotechnology Approaches to Modern Vaccine Design <i>George P Lomonosoff and Daniel Ponndorf</i>	662
Viruses: Impact on Science and Society <i>Neeraja Sankaran and Robin A Weiss</i>	671

VOLUME 2

Viruses as Infectious Agents: Human and Animal Viruses

Adenoviruses (<i>Adenoviridae</i>) <i>Balázs Harrach and Mária Benkő</i>	3
---	---

African Horse Sickness Virus (<i>Reoviridae</i>) <i>Piet A van Rijn</i>	17
African Swine Fever Virus (<i>Asfarviridae</i>) <i>Linda K Dixon, Rachel Nash, Philippa C Hawes, and Christopher L Netherton</i>	22
Akabane Virus and Schmallenberg Virus (<i>Peribunyaviridae</i>) <i>Martin Beer and Kerstin Wernike</i>	34
Alphaviruses Causing Encephalitis (<i>Togaviridae</i>) <i>Diane E Griffin</i>	40
Anelloviruses (<i>Anelloviridae</i>) <i>Fabrizio Maggi and Mauro Pistello</i>	48
Animal Lentiviruses (<i>Retroviridae</i>) <i>Esperanza Gomez-Lucia</i>	56
Animal Morbilliviruses (<i>Paramyxoviridae</i>) <i>Carina Conceicao and Dalan Bailey</i>	68
Animal Papillomaviruses (<i>Papillomaviridae</i>) <i>John S Munday</i>	79
Astroviruses (<i>Astroviridae</i>) <i>Virginia Hargest, Amy Davis, and Stacey Schultz-Cherry</i>	92
Avian Hepadnaviruses (<i>Hepadnaviridae</i>) <i>Allison R Jilbert, Georget Y Reaiche-Miller, and Catherine A Scougall</i>	100
Avian Herpesviruses (<i>Herpesviridae</i>) <i>Vishwanatha RAP Reddy and Venugopal Nair</i>	112
Avian Influenza Viruses (<i>Orthomyxoviridae</i>) <i>Nicolas Bravo-Vasquez and Stacey Schultz-Cherry</i>	117
Avian Leukosis and Sarcoma Viruses (<i>Retroviridae</i>) <i>Karen L Beemon</i>	122
Bluetongue Virus (<i>Reoviridae</i>) <i>Raghavendran Kulasegaran-Shylini and Polly Roy</i>	127
Borna Disease Virus and Related Bornaviruses (<i>Bornaviridae</i>) <i>Susan L Payne</i>	137
Bovine Leukemia Virus (<i>Retroviridae</i>) <i>Thomas Joris, Roghaiyeh Safari, Jean-Rock Jacques, and Luc Willems</i>	144
Bovine Viral Diarrhea, Border Disease, and Classical Swine Fever Viruses (<i>Flaviviridae</i>) <i>Paul Becher, Volker Moennig, and Norbert Tautz</i>	153
Capripoxviruses, Parapoxviruses, and Other Poxviruses of Ruminants (<i>Poxviridae</i>) <i>Philippa M Beard</i>	165
Chikungunya Virus (<i>Togaviridae</i>) <i>Thomas E Morrison and Stephanie E Ander</i>	173
Circoviruses (<i>Circoviridae</i>) <i>Giovanni Franzo and Joaquim Segalés</i>	182
Coronaviruses: General Features (<i>Coronaviridae</i>) <i>Paul Britton</i>	193
Coronaviruses: Molecular Biology (<i>Coronaviridae</i>) <i>X Deng and SC Baker</i>	198

Crimean-Congo Hemorrhagic Fever Virus and Nairoviruses of Medical Importance (<i>Nairoviridae</i>) <i>Ali Mirazimi, Felicity Burt, and Anna Papa</i>	208
Dengue Viruses (<i>Flaviviridae</i>) <i>Ashley L. St. John and Duane J. Gubler</i>	218
Ebola Virus (<i>Filoviridae</i>) <i>Andrea Marzi and Logan Banadyga</i>	232
Enteroviruses (<i>Picornaviridae</i>) <i>Carita Savolainen-Kopra, Soile Blomqvist, and Petri Susi</i>	245
Enveloped, Positive-Strand RNA Viruses (<i>Nidovirales</i>) <i>L. Enjuanes, AE Gorbalenya, RJ de Groot, JA Cowley, J Ziebuhr, and EJ Snijder</i>	256
Epstein-Barr Virus (<i>Herpesviridae</i>) <i>Lawrence S. Young</i>	267
Equine Herpesviruses (<i>Herpesviridae</i>) <i>Gisela Soboll-Hussey, Nikolaus Osterrieder, and Walid Azab</i>	278
Equine, Canine, and Swine Influenza (<i>Orthomyxoviridae</i>) <i>Janet M. Daly and Japhette E. Kembou-Ringert</i>	287
Feline Calicivirus (<i>Caliciviridae</i>) <i>Margaret J. Hosie and Michaela J. Conley</i>	294
Feline Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>Brian J. Willett and Margaret J. Hosie</i>	300
Fish and Amphibian Alloherpesviruses (<i>Herpesviridae</i>) <i>Maxime Boutier, Léa Morvan, Natacha Delrez, Francesco Origi, Andor Doszpoly, and Alain Vanderplasschen</i>	306
Fish Retroviruses (<i>Retroviridae</i>) <i>TA Paul, RN Casey, PR Bowser, JW Casey, J Rovnak, and SL Quackenbush</i>	316
Fish Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Gael Kurath and David Stone</i>	324
Foot-and-Mouth Disease Viruses (<i>Picornaviridae</i>) <i>David J. Rowlands</i>	332
Fowlpox Virus and Other Avipoxviruses (<i>Poxviridae</i>) <i>Efstathios S. Giotis and Michael A. Skinner</i>	343
Hantaviruses (<i>Hantaviridae</i>) <i>Tarja Sironen and Antti Vaheri</i>	349
Henipaviruses (<i>Paramyxoviridae</i>) <i>Lin-Fa Wang and Danielle E. Anderson</i>	355
Hepatitis A Virus (<i>Picornaviridae</i>) <i>Andreas Dotzauer</i>	362
Hepatitis B Virus (<i>Hepadnaviridae</i>) <i>Peter Karayiannis</i>	373
Hepatitis C Virus (<i>Flaviviridae</i>) <i>Ralf Bartenschlager and Keisuke Tabata</i>	386
Hepeviruses (<i>Hepeviridae</i>) <i>Xiang-Jin Meng</i>	397
Herpes Simplex Virus 1 and 2 (<i>Herpesviridae</i>) <i>David M. Knipe and Richard Whitley</i>	404

History of Virology: Vertebrate Viruses <i>F Fenner</i>	414
Human Boca- and Protoparvoviruses (<i>Parvoviridae</i>) <i>Maria Söderlund-Venermo and Jianming Qiu</i>	419
Human Coronavirus-229E, -OC43, -NL63, and -HKU1 (<i>Coronaviridae</i>) <i>Ding X Liu, Jia Q Liang, and To S Fung</i>	428
Human Cytomegalovirus (<i>Herpesviridae</i>) <i>Edward S Mocarski</i>	441
Human Immunodeficiency Virus (<i>Retroviridae</i>) <i>Blaide Woodburn, Ann Emery, and Ronald Swanstrom</i>	460
Human Metapneumovirus (<i>Pneumoviridae</i>) <i>Antonella Casola, Matteo P Garofalo, and Xiaoyong Bao</i>	475
Human Norovirus and Sapovirus (<i>Caliciviridae</i>) <i>Sumit Sharma, Marie Hagbom, Lennart Svensson, and Johan Nordgren</i>	483
Human Papillomaviruses (<i>Papillomaviridae</i>) <i>Alison A McBride and Samuel S Porter</i>	493
Human Parainfluenza Viruses (<i>Paramyxoviridae</i>) <i>Elisabeth Adderson</i>	502
Human Pathogenic Arenaviruses (<i>Arenaviridae</i>) <i>Sheli R Radoshitzky and Juan C de la Torre</i>	507
Human Polyomaviruses (<i>Papillomaviridae</i>) <i>Melissa S Maginnis</i>	518
Human T-Cell Leukemia Virus-1 and -2 (<i>Retroviridae</i>) <i>Amanda R Panfil and Patrick L Green</i>	528
Infectious Bursal Disease Virus (<i>Birnaviridae</i>) <i>Daral J Jackwood</i>	540
Infectious Pancreatic Necrosis Virus (<i>Birnaviridae</i>) <i>Øystein Evensen</i>	544
Influenza A Viruses (<i>Orthomyxoviridae</i>) <i>Laura Kakkola, Niina Ikonen, and Ilkka Julkunen</i>	551
Influenza B, C and D Viruses (<i>Orthomyxoviridae</i>) <i>Thorsten Wolff and Michael Veit</i>	561
Jaagsiekte Sheep Retrovirus (<i>Retroviridae</i>) <i>James M Sharp, Marcelo De las Heras, Massimo Palmarini, and Thomas E Spencer</i>	575
Japanese Encephalitis Virus (<i>Flaviviridae</i>) <i>Sang-Im Yun and Young-Min Lee</i>	583
Kaposi's Sarcoma-Associated Herpesvirus (<i>Herpesviridae</i>) <i>Anne K Cordes and Thomas F Schulz</i>	598
Marburg and Ravn Viruses (<i>Filoviridae</i>) <i>Courtney Woolsey, Thomas W Geisbert, and Robert W Cross</i>	608
Measles Virus (<i>Paramyxoviridae</i>) <i>Roberto Cattaneo and Michael McChesney</i>	619
Molluscum Contagiosum Virus (<i>Poxviridae</i>) <i>Joachim J Bugert and Rosina Ehmann</i>	629

Mumps Virus (<i>Paramyxoviridae</i>) <i>Stephen A Winchester and Kevin E Brown</i>	634
Murine Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>George R Young and Kate N Bishop</i>	643
Newcastle Disease Virus (<i>Paramyxoviridae</i>) <i>Ben Peeters and Guus Koch</i>	648
Orthobunyaviruses (<i>Peribunyaviridae</i>) <i>Alyssa B Evans, Clayton W Winkler, and Karin E Peterson</i>	654
Parapoxviruses (<i>Poxviridae</i>) <i>Hanns-Joachim Rziha and Mathias Büttner</i>	666
Parechoviruses (<i>Picornaviridae</i>) <i>Sisko Tauriainen and Glyn Stanway</i>	675
Parvoviruses of Carnivores, and the Emergence of Canine Parvovirus (<i>Parvoviridae</i>) <i>Colin R Parrish, Ian EH Voorhees, and Susan L Hafenstein</i>	683
Polioviruses (<i>Picornaviridae</i>) <i>Philip D Minor</i>	688
Porcine Reproductive and Respiratory Syndrome Virus and Equine Arteritis Virus (<i>Arteriviridae</i>) <i>Jianqiang Zhang, Alan T Loynachan, Gregory W Stevenson, and Jeffrey J Zimmerman</i>	697
Prions of Vertebrates <i>Jonathan DF Wadsworth and John Collinge</i>	707
Pseudorabies Virus (<i>Herpesviridae</i>) <i>Thomas C Mettenleiter and Barbara G Klupp</i>	714
Rabbit Hemorrhagic Disease Virus and European Brown Hare Syndrome Virus (<i>Caliciviridae</i>) <i>Lorenzo Capucci, Patrizia Cavadini, and Antonio Lavazza</i>	724
Rabbit Myxoma Virus and the Fibroma Viruses (<i>Poxviridae</i>) <i>Peter J Kerr</i>	730
Rabies and Other Lyssaviruses (<i>Rhabdoviridae</i>) <i>Ashley C Banyard and Anthony R Fooks</i>	738
Respiratory Syncytial Virus (<i>Pneumoviridae</i>) <i>Tiffany King, Tiffany Jenkins, Supranee Chaiwatpongsakorn, and Mark E Peebles</i>	747
Rhinoviruses (<i>Picornaviridae</i>) <i>Matti Waris and Olli Ruuskanen</i>	757
Rift Valley Fever Virus and Other Phleboviruses (<i>Phenuiviridae</i>) <i>Tetsuro Ikegami</i>	765
Roseoloviruses: Human Herpesviruses 6A, 6B and 7 (<i>Herpesviridae</i>) <i>Katherine N Ward</i>	778
Rotaviruses (<i>Reoviridae</i>) <i>Juana Angel and Manuel A Franco</i>	789
Rubella Virus (<i>Picornaviridae</i>) <i>Annette Mankertz</i>	797
Saint Louis Encephalitis Virus (<i>Flaviviridae</i>) <i>William K Reisen, Lark L Coffey, Daniele M Swetnam, and Aaron C Brault</i>	805
Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS) (<i>Coronaviridae</i>) <i>Joseph SM Peiris and Leo LM Poon</i>	814

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) (<i>Coronaviridae</i>) <i>Malik Peiris</i>	825
Simian Immunodeficiency Virus (SIV) and HIV-2 (<i>Retroviridae</i>) <i>Phyllis J Kanki</i>	827
Sindbis Virus (<i>Togaviridae</i>) <i>Satu Kurkela</i>	837
Tick-Borne Encephalitis Virus (<i>Flaviviridae</i>) <i>Teemu Smura, Suvi Kuivanen, and Olli Vapalahti</i>	843
Transmissible Gastroenteritis Virus of Pigs and Porcine Epidemic Diarrhea Virus (<i>Coronaviridae</i>) <i>Qiang Liu and Volker Gerds</i>	850
Vaccinia Virus (<i>Poxviridae</i>) <i>Yan Xiang and Rebecca K Lane</i>	854
Varicella-Zoster Virus (<i>Herpesviridae</i>) <i>Jeffrey I Cohen</i>	860
Variola and Monkeypox Viruses (<i>Poxviridae</i>) <i>Lalita Priyamvada and Panayampalli S Satheshkumar</i>	868
Vesicular Stomatitis Virus and Bovine Ephemeral Fever Virus (<i>Rhabdoviridae</i>) <i>Peter J Walker and Robert B Tesh</i>	875
West Nile Virus (<i>Flaviviridae</i>) <i>Fengwei Bai and Elizabeth Ashley Thompson</i>	884
Yellow Fever Virus (<i>Flaviviridae</i>) <i>Ashley E Strother and Alan DT Barrett</i>	891
Zika Virus (<i>Flaviviridae</i>) <i>Nikos Vasilakis, Shannan L Rossi, Sasha R Azar, Irma E Cisneros, Cassia F Estofolete, and Mauricio L Nogueira</i>	899

VOLUME 3

Viruses as Infectious Agents: Plant Viruses

An Introduction to Plant Viruses <i>Roger Hull</i>	3
Emerging and Re-Emerging Plant Viruses <i>Sabrina Bertin, Francesco Faggioli, Andrea Gentili, Ariana Manglli, Anna Taglienti, Antonio Tiberini, and Laura Tomassoli</i>	8
Emerging Geminiviruses (<i>Geminiviridae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, and Muhammad Mubin</i>	21
Movement of Viruses in Plants <i>Manfred Heinlein</i>	32
Plant Antiviral Defense: Gene-Silencing Pathways <i>Vitantonio Pantaleo, Chikara Masuta, and Hanako Shimura</i>	43
Plant Resistance to Viruses: Engineered Resistance <i>Marc Fuchs</i>	52
Plant Resistance to Viruses: Natural Resistance Associated With Dominant Genes <i>Mandy Ravensbergen and Richard Kormelink</i>	60

Plant Resistance to Viruses: Natural Resistance Associated With Recessive Genes <i>Masayoshi Hashimoto, Kensaku Maejima, Yasuyuki Yamaji, and Shigetou Namba</i>	69
Plant Viral Diseases: Economic Implications <i>Basavaprabhu L Patil</i>	81
Retrotransposons of Plants <i>M-A Grandbastien</i>	98
Vector Transmission of Plant Viruses <i>Etienne Herrbach and Quentin Chesnais</i>	106
Viral Suppressors of Gene Silencing <i>Hernan Garcia-Ruiz</i>	116
Virus-Induced Gene Silencing (VIGS) <i>Xu Tengzhi, Ugrappa Nagalakshmi, and Savithramma P Dinesh-Kumar</i>	123
Alfalfa Mosaic Virus (<i>Bromoviridae</i>) <i>L Sue Loesch-Fries</i>	132
Alphaflexiviruses (<i>Alphaflexiviridae</i>) <i>Sergey Y Morozov and Alexey A Agranovsky</i>	140
Alphasatellites (<i>Alphasatellitidae</i>) <i>Rob W Briddon and Muhammad S Nawaz-ul-Rehman</i>	149
Amalgaviruses (<i>Amalgaviridae</i>) <i>Ioannis E Tzanetakis, Sead Sabanadzovic, and Rodrigo A Valverde</i>	154
Badnaviruses (<i>Caulimoviridae</i>) <i>Andrew DW Geering</i>	158
Banana Bunchy Top Virus (<i>Nanoviridae</i>) <i>John E Thomas</i>	169
Barley Yellow Dwarf Viruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	176
Bean Common Mosaic Virus and Bean Common Mosaic Necrosis Virus (<i>Potyviridae</i>) <i>Ramon Jordan and John Hammond</i>	184
Bean Golden Mosaic Virus and Bean Golden Yellow Mosaic Virus (<i>Geminiviridae</i>) <i>Francisco M Zerbini and Simone G Ribeiro</i>	192
Beet Curly Top Virus (<i>Geminiviridae</i>) <i>Robert L Gilbertson, Tomas A Melgarejo, Maria R Rojas, William M Wintermantel, and John Stanley</i>	200
Beet Necrotic Yellow Vein Virus (<i>Benyviridae</i>) <i>Sebastian Liebe, Annette Niehl, Renate Koenig, and Mark Varrelmann</i>	213
Benyviruses (<i>Benyviridae</i>) <i>Annette Niehl, Sebastian Liebe, Mark Varrelmann, and Renate Koenig</i>	219
Betaflexiviruses (<i>Betaflexiviridae</i>) <i>Nobuyuki Yoshikawa and Hajime Yaegashi</i>	229
Betasatellites and Deltasatellites (<i>Toleusatellitidae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, Muhammad Hassan, and Muhammad Mubin</i>	239
Bluner-, Cile-, and Higreviruses (<i>Kitaviridae</i>) <i>Diego F Quito-Avila, Juliana Freitas-Astúa, and Michael J Melzer</i>	247
Brome Mosaic Virus (<i>Bromoviridae</i>) <i>Guijuan He, Zhenlu Zhang, Preethi Sathanantham, Arturo Diaz, and Xiaofeng Wang</i>	252

Bromoviruses (<i>Bromoviridae</i>) <i>Jozef J Bujarski</i>	260
Bymoviruses (<i>Potyviridae</i>) <i>Annette Niehl and Frank Rabenstein</i>	268
Cacao Swollen Shoot Virus (<i>Caulimoviridae</i>) <i>Emmanuelle Muller</i>	274
Carmo-Like Viruses (<i>Tombusviridae</i>) <i>Miryam Pérez-Cañamás and Carmen Hernández</i>	285
Cassava Brown Streak Viruses (<i>Potyviridae</i>) <i>Basavaprabhu L Patil</i>	293
Cassava Mosaic Viruses (<i>Geminiviridae</i>) <i>James Legg and Stephan Winter</i>	301
Caulimoviruses (<i>Caulimoviridae</i>) <i>James E Schoelz and Mustafa Adhab</i>	313
Cheraviruses, Sadwaviruses and Torradoviruses (<i>Secoviridae</i>) <i>Toru Iwanami and René AA van der Vlugt</i>	322
Citrus Tristeza Virus (<i>Closteroviridae</i>) <i>Moshe Bar-Joseph, Scott J Harper, and William O Dawson</i>	327
Closteroviruses (<i>Closteroviridae</i>) <i>Marc Fuchs</i>	336
Comoviruses and Fabaviruses (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	348
Cotton Leaf Curl Disease (<i>Geminiviridae</i>) <i>Nasim Ahmed, Imran Amin, and Shahid Mansoor</i>	355
Cowpea Mosaic Virus (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	364
Cucumber Mosaic Virus (<i>Bromoviridae</i>) <i>Judith Hirsch and Benoît Moury</i>	371
Dianthovirus (<i>Tombusviridae</i>) <i>Kiwamu Hyodo and Masanori Kaido</i>	383
Endornaviruses (<i>Endornaviridae</i>) <i>Toshiyuki Fukuhara</i>	388
Fimoviruses (<i>Fimoviridae</i>) <i>Toufic Elbeaino and Michele Digiaro</i>	396
Furoviruses (<i>Virgaviridae</i>) <i>Annette Niehl and Renate Koenig</i>	405
Geminiviruses (<i>Geminiviridae</i>) <i>Jesús Navas-Castillo and Elvira Fiallo-Olivé</i>	411
Hordeiviruses (<i>Virgaviridae</i>) <i>Zhihao Jiang, Meng Yang, Yongliang Zhang, Andrew O Jackson, and Dawei Li</i>	420
Idaeoviruses (<i>Mayoviridae</i>) <i>Robert R Martin and Karen E Keller</i>	430
Illaviruses (<i>Bromoviridae</i>) <i>Aaron Simkovich, Susanne E Kohalmi, and Aiming Wang</i>	439

Luteoviruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	447
Machlomovirus and Panicoviruses (<i>Tombusviridae</i>) <i>Kay Scheets</i>	456
Maize Streak Virus (<i>Geminiviridae</i>) <i>Darren P Martin and Aderito L Monjane</i>	461
Nanoviruses (<i>Nanoviridae</i>) <i>Bruno Gronenborn and H Josef Vetten</i>	470
Necro-Like Viruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Giovanni P Martelli[†]</i>	481
Nepoviruses (<i>Secoviridae</i>) <i>Hélène Sanfaçon</i>	486
Ophioviruses (<i>Aspiviridae</i>) <i>Anna M Vaira and John Hammond</i>	495
Orthospoviruses (<i>Tospoviridae</i>) <i>Renato O Resende and Hanu R Pappu</i>	507
Ourmiaviruses (<i>Botourmiaviridae</i>) <i>Gian Paolo Accotto and Cristina Rosa</i>	516
Papaya Ringspot Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	520
Pecluviruses (<i>Virgaviridae</i>) <i>Hema Masarapu, Pothur Sreenivasulu, Philippe Delfosse, Claude Bragard, Anne Legreve, and DVR Reddy</i>	528
Pepino Mosaic Virus (<i>Alphaflexiviridae</i>) <i>Rene AA van der Vlugt and CCMM Stijger</i>	539
Plant Reoviruses (<i>Reoviridae</i>) <i>Yu Huang and Yi Li</i>	545
Plant Resistance to Geminiviruses <i>Basavaprabhu L Patil, Supriya Chakraborty, Henryk Czosnek, Elvira Fiallo-Olivé, Robert L Gilbertson, James Legg, Shahid Mansoor, Jesús Navas-Castillo, Rubab Z Naqvi, Saleem U Rahman, and Francisco M Zerbini</i>	554
Plant Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Ralf G Dietzgen, Michael M Goodin, and Zhenghe Li</i>	567
Plant Satellite Viruses (<i>Albetovirus, Aumaivirus, Papanivirus, Virtovirus</i>) <i>Mart Krupovic</i>	581
Plum Pox Virus (<i>Potyviridae</i>) <i>Miroslav Glasa and Thierry Candresse</i>	586
Poleroviruses (<i>Luteoviridae</i>) <i>Hernan Garcia-Ruiz, Natalie M Holste, and Katherine LaTourrette</i>	594
Pomoviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	603
Potato Virus Y (<i>Potyviridae</i>) <i>Laurent Glais and Benoît Moury</i>	612
Potexviruses (<i>Alphaflexiviridae</i>) <i>Ki H Ryu, Eun G Song, and Jin S Hong</i>	623

[†]Deceased.

Potyviruses (<i>Potyviridae</i>) <i>Adrián Valli, Juan A García, and Juan J López-Moya</i>	631
Quinviruses (<i>Betaflexiviridae</i>) <i>Ki H Ryu and Eun G Song</i>	642
Reverse-Transcribing Viruses (<i>Belpaoviridae, Metaviridae, and Pseudoviridae</i>) <i>Carlos Llorens, Beatriz Soriano, Maria A Navarrete-Muñoz, Ahmed Hafez, Vicente Arnau, Jose Miguel Benito, Toni Gabaldon, Norma Rallon, Jaume Pérez-Sánchez, and Mart Krupovic</i>	653
Rice Tungro Disease (<i>Secoviridae, Caulimoviridae</i>) <i>Gaurav Kumar, Fauzia Zarreen, and Indranil Dasgupta</i>	667
Rice Yellow Mottle Virus (<i>Solemoviridae</i>) <i>Eugénie Hébrard, Nils Poulicard, and Mbolarinosy Rakotomalala</i>	675
Satellite Nucleic Acids and Viruses <i>Olufemi J Alabi, Alfredo Diaz-Lara, and Maher Al Rwahnih</i>	681
Secoviruses (<i>Secoviridae</i>) <i>Jeremy R Thompson</i>	692
Sequiviruses and Waikaviruses (<i>Secoviridae</i>) <i>Lucy Rae Stewart</i>	703
Solemoviruses (<i>Solemoviridae</i>) <i>Cecilia Sarmiento, Merike Sõmera, and Erkki Truve[†]</i>	712
Tenuiviruses (<i>Phenuiviridae</i>) <i>Bertha Cecilia Ramirez and Anne-Lise Haenni</i>	719
Tobacco Mosaic Virus (<i>Virgaviridae</i>) <i>Marc HV Van Regenmortel</i>	727
Tobamoviruses (<i>Virgaviridae</i>) <i>Ulrich Melcher, Dennis J Lewandowski, and William O Dawson</i>	734
Tobraviruses (<i>Virgaviridae</i>) <i>Stuart A MacFarlane</i>	743
Tomato Leaf Curl New Delhi Virus (<i>Geminiviridae</i>) <i>Supriya Chakraborty and Manish Kumar</i>	749
Tomato Spotted Wilt Virus (<i>Tospoviridae</i>) <i>Hanu R Pappu, Anna E Whitfield, and Athos S de Oliveira</i>	761
Tomato Yellow Leaf Curl Viruses (<i>Geminiviridae</i>) <i>Henryk Czosnek</i>	768
Tombusvirus-Like Viruses (<i>Tombusviridae</i>) <i>K Andrew White</i>	778
Tombusviruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Kay Scheets</i>	788
Tritimoviruses and Rymoviruses (<i>Potyviridae</i>) <i>Satyanarayana Tatineni and Gary L Hein</i>	797
Triviruses (<i>Betaflexiviridae</i>) <i>Yahya ZA Gaafar and Heiko Ziebell</i>	805
Tymoviruses (<i>Tymoviridae</i>) <i>Rosemarie W Hammond and Peter Abrahamian</i>	818

[†]Deceased.

Umbraviruses (<i>Tombusviridae</i>) <i>Eugene V Ryabov and Michael E Taliansky</i>	827
Varicosaviruses (<i>Rhabdoviridae</i>) <i>Takahide Sasaya</i>	833
Virgaviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	839
Viroids (<i>Pospiviroidae</i> and <i>Avsunviroidae</i>) <i>Ricardo Flores and Robert A Owens</i>	852
Watermelon Mosaic Virus and Zucchini Yellow Mosaic Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	862

VOLUME 4

Viruses as Infectious Agents: Bacterial, Archaeal, Fungal, Algal, and Invertebrate Viruses

Bacterial Viruses

History of Virology: Bacteriophages <i>William C Summers</i>	3
Icosahedral Phages – Single-Stranded DNA (ϕ X174) <i>Bentley A Fane and Aaron P Roznowski</i>	10
Single-Stranded RNA Bacterial Viruses <i>Peter G Stockley and Junjie Zhang</i>	21
Enveloped Icosahedral Phages – Double-Stranded RNA (ϕ 6) <i>Paul Gottlieb and Aleksandra Alimova</i>	26
Membrane-Containing Icosahedral DNA Bacteriophages <i>Roman Tuma, Sarah J Butcher, and Hanna M Oksanen</i>	36
Tailed Double-Stranded DNA Phages <i>Robert L Duda</i>	45
Helical and Filamentous Phages <i>Andreas Kuhn and Sebastian Leptihn</i>	53
Replication of <i>Bacillus</i> Double-Stranded DNA Bacteriophages <i>Silvia Ayora, Paulo Tavares, Ruben Torres, and Juan C Alonso</i>	61
Lytic Transcription <i>William McAllister and Deborah M Hinton</i>	69
Lysogeny <i>Keith E Shearwin and Jia Q Truong</i>	77
Decision Making by Temperate Phages <i>Ido Golding, Seth Coleman, Thu VP Nguyen, and Tianyou Yao</i>	88
Mobilization of Phage Satellites <i>Kristen N LeGault and Kimberley D Seed</i>	98
Portal Vertex <i>Peng Jing and Mauricio Cortes Jr.</i>	105

Prohead, the Head Shell Pre-Cursor <i>Marc C Morais and Michael E Woodson</i>	115
Enzymology of Viral DNA Packaging Machines <i>Carlos E Catalano</i>	124
DNA Packaging: DNA Recognition <i>Sandra J Greive and Oliver W Bayfield</i>	136
DNA Packaging: The Translocation Motor <i>Janelle A Hayes and Brian A Kelch</i>	148
Biophysics of DNA Packaging <i>Joshua Pajak, Gaurav Arya, and Douglas E Smith</i>	160
Energetics of the DNA-Filled Head <i>Alex Evilevitch</i>	167
Bacteriophage Receptor Proteins of Gram-Negative Bacteria <i>Sarah M Doore, Kristin N Parent, Sundharraman Subramanian, Jason R Schrad, and Natalia B Hubbs</i>	175
Tail Structure and Dynamics <i>Shweta Bhatt, Petr G Leiman, and Nicholas MI Taylor</i>	186
Bacteriophage Tail Fibres, Tailspikes, and Bacterial Receptor Interaction <i>Mateo Seoane-Blanco, Mark J van Raaij, and Meritxell Granell</i>	194
Phage Genome and Protein Ejection In Vivo <i>Ian J Molineux, L Letti Lopez, and Aaron P Roznowski</i>	206
Dealing With the Whole Head: Diversity and Function of Capsid Ejection Proteins in Tailed Phages <i>Lindsay W Black and Julie A Thomas</i>	219
Jumbo Phages <i>Isaac T Younker and Carol Duffy</i>	229
CRISPR-Cas Systems and Anti-CRISPR Proteins: Adaptive Defense and Counter-Defense in Prokaryotes and Their Viruses <i>Asma Hatoum-Aslan and Olivia G Howell</i>	242
Bacteriophage: Therapeutics and Diagnostics Development <i>Teng-Chieh Yang</i>	252
Bacteriophage Vaccines <i>Pan Tao and Venigalla B Rao</i>	259
Bacteriophage Diversity <i>Julianne H Grose and Sherwood R Casjens</i>	265
Genetic Mosaicism in the Tailed Double-Stranded DNA Phages <i>Welkin H Pope</i>	276
Bacteriophages of the Human Microbiome <i>Pilar Manrique, Michael Dills, and Mark J Young</i>	283
Bacteriophage: Red Recombination System and the Development of Recombineering Technologies <i>Lynn C Thomason and Kenan C Murphy</i>	291
Nanotechnology Application of Bacteriophage DNA Packaging Nanomotors <i>Tao Weitao, Lixia Zhou, Zhefeng Li, Long Zhang, and Peixuan Guo</i>	302
General Ecology of Bacteriophages <i>Stephen T Abedon</i>	314
Marine Bacteriophages <i>Vera Bischoff, Falk Zucker, and Cristina Moraru</i>	322

Ecology of Phages in Extreme Environments <i>Tatiana A Demina and Nina S Atanasova</i>	342
---	-----

Archaeal Viruses

Diversity of Hyperthermophilic Archaeal Viruses <i>David Prangishvili, Mart Krupovic, and Diana P Baquero</i>	359
Euryarchaeal Viruses <i>Tatiana A Demina and Hanna M Oksanen</i>	368
Vesicle-Like Archaeal Viruses <i>Elina Roine and Nina S Atanasova</i>	380
Virus–Host Interactions in Archaea <i>Diana P Baquero, David Prangishvili, and Mart Krupovic</i>	387
Antiviral Defense Mechanisms in Archaea <i>Qunxin She</i>	400
Discovery of Archaeal Viruses in Hot Spring Environments Using Viral Metagenomics <i>Jennifer Wirth, Jacob H Munson-McGee, and Mark J Young</i>	407
Metagenomes of Archaeal Viruses in Hypersaline Environments <i>Fernando Santos, María D Ramos-Barbero, and Josefa Antón</i>	414
Extreme Environments as a Model System to Study How Virus–Host Interactions Evolve Along the Symbiosis Continuum <i>Samantha J DeWerff and Rachel J Whitaker</i>	419

Fungal Viruses

An Introduction to Fungal Viruses <i>Nobuhiro Suzuki</i>	431
Cross-Kingdom Virus Infection <i>Liyang Sun, Hideki Kondo, and Ida Bagus Andika</i>	443
Diversity of Mycoviruses in Aspergilli <i>Ioly Kotta-Loizou</i>	450
Evolution of Mycoviruses <i>Mahtab Peyambari, Vaskar Thapa, and Marilyn J Roossinck</i>	457
Mixed Infections of Mycoviruses in Phytopathogenic Fungus <i>Sclerotinia sclerotiorum</i> <i>Jiatao Xie and Daohong Jiang</i>	461
Mycovirus-Mediated Biological Control <i>Daniel Rigling, Cécile Robin, and Simone Prospero</i>	468
Mycoviruses With Filamentous Particles <i>Michael N Pearson</i>	478
Prions of Yeast and Fungi <i>Reed B Wickner and Herman K Edskes</i>	487
Single-Stranded DNA Mycoviruses <i>Daohong Jiang</i>	493
Structure of Double-Stranded RNA Mycoviruses <i>José R Castón, Nobuhiro Suzuki, and Said A Ghabrial[†]</i>	504

[†]Deceased.

<i>Ustilago maydis</i> Viruses and Their Killer Toxins <i>Alexis Williams and Thomas J Smith</i>	513
Vegetative Incompatibility in Filamentous Fungi <i>Songsong Wu, Daohong Jiang, and Jiatao Xie</i>	520

Nomenclature

AdV Adenovirus

bp Base pair

HAdV Human adenovirus

kbp Kilo base pair, 1000 bp

SAdV Simian adenovirus

Glossary

CAR A cellular receptor characterized by its property that Coxsackie virus and many adenovirus types attach to it.

Co-evolution The continuous parallel evolution of a host and its virus, consequently showing similar phylogeny (evolutionary tree topology).

Fiber Antenna like projections from the adenovirus virions, which is used to attach the virus to the cells.

PCR Polymerase chain reaction is a molecular biological method to make many copies of a specific DNA segment.

Phylogenetics The study of the evolutionary history and relationships among groups of organisms.

Squamata The largest order of reptiles, comprising lizards, snakes and amphisbaenians (worm lizards) collectively called squamates or scaled reptiles.

Adenoviruses (AdVs) are middle-sized, nonenveloped, icosahedral, double-stranded DNA viruses of vertebrates. The prefix adeno comes from the Greek word *ádēn* (gland), reflecting the first isolation of a virus of this type from human adenoid tissue 67 years ago. AdVs have since been isolated from many hosts, including representatives of every major vertebrate class from fish to mammals. Thanks to the polymerase chain reaction (PCR), a rapidly increasing number of novel AdVs is being detected in wild life, but isolation and in vitro propagation of such viruses are usually hampered by the lack of appropriate permissive cell cultures. Certain AdVs can cause disease or even death in humans or animals; nonetheless they are mostly harmless in non-immuno-compromised, healthy individuals. AdVs have been used as model organisms in molecular biology, and important findings of general relevance have emerged from such studies, including the phenomenon of splicing in eukaryotes. AdVs have become one of the most popular vector systems for virus-based gene therapy and vaccination and have potential as antitumor tools. Wide prevalence in diverse host species and a substantially conserved genome organization make AdVs an ideal model for studying virus evolution.

Classification

Adenoviruses (AdVs) belong to the family *Adenoviridae*. Very recently, higher taxonomical levels have been introduced: realm *Varidnaviria*, kingdom *Bamfordvirae*, phylum *Preplasmiviricota*, class *Tectiliviricetes*, order *Rowavirales*. This is based on similarities to other viruses and consequently on their anticipated evolutionary history. Thus certain bacterial viruses, namely the 'bacteriophages' in *Tectiviridae*, and also a virus of archaea living in hot springs (Sulfolobus turreted icosahedral virus, *Turriviridae*), and the green alga virus *Paramecium bursaria Chlorella virus 1* (*Phycodnaviridae*) were described as having common evolutionary roots with AdVs. *Adenoviridae*, *Tectiviridae*, *Turriviridae* with bacteriophages classified into *Corticoviridae* are grouped into a common class, and with *Phycodnaviridae* and additional families into a common kingdom based mainly on their double jelly-roll major capsid protein.

There are five official genera and one pending genus in the family. Four genera (*Mastadenovirus*, *Aviadenovirus*, *Ichadenovirus*, and *Testadenovirus*) comprise AdVs that are hypothesized to have likely co-evolved with the host, namely mammals, birds, fish, and turtles (testudines), respectively. The remaining two genera (*Atadenovirus* and *Siadenovirus*) have broader host range. *Atadenoviruses* were named after the bias (toward high A + T) in the genome of their initial representatives, found in various ruminant and avian hosts, as well as in a marsupial-associated sample. However, every known AdV detected in squamate hosts (lizards, snakes, and worm lizards) also belongs to this genus. The base composition of the DNA of the squamate-reptilian AdVs is equilibrated. *Siadenoviruses* were isolated from, or detected by PCR in, birds, a frog, and a few tortoise species. This genus was named after the presence of a gene encoding a putative sialidase; however novel *siadenoviruses*, detected in penguins recently, were found devoid of this gene.

Within each genus, the viruses are grouped into species, which are labeled with the name of the host and the genus, supplemented with letters of the alphabet, e.g., *Human mastadenovirus D* (Table 1). Host origin is only one of several criteria that are used to demarcate the species. Phylogenetic distance is the most significant criterion, with species defined as being separated by more than 10%–15% amino acid sequence divergence of the DNA polymerase by maximum likelihood analysis. Genome organization characteristics is another important criterion, yet additional traits such as the G + C content, cross-neutralization values, biological characteristics including pathogenicity, hemagglutination properties and the ability to recombine, are considered, too. Ideally, all these ancillary data are consistent with the results of the phylogenetic calculations.

Table 1 The taxonomy of family Adenoviridae^a

^aAvailable full genome sequences are noted by + or by the type number of the sequenced serotype(s) if those listed are not all sequenced and available. In case of the common name of 'simian AdV', two letter abbreviations show the original hosts: bo, bonobo; ch, chimpanzee; cy, cynomolgus monkey (crab-eating macaque); go, gorilla; gr, grivet; gs, golden snub-nosed monkey; m, macaque sp.; rh, rhesus macaque; yb, yellow baboon.

Along these rules, e.g., chimpanzee AdVs are classified into different human AdV species. Human AdVs have been studied the most extensively and are grouped into seven species (*Human mastadenovirus A* to *Human mastadenovirus G*; abbreviated informally to HAdV–A to HAdV–G). The species are further subdivided to numbered (sero)types, abbreviated in a hyphenated form such as e.g., HAdV–5.

The AdV taxonomy, i.e., clustering similar AdVs together, while separating those that are 'adequately' different, and especially correct naming of the taxa, is prone to human errors and discussions partly because of the lack of knowledge available at a certain time point. As we discover novel AdVs, we find that several AdV types are capable of crossing species barriers of different levels. Thus, some names referring to hosts will not be correct or the best description in the future. Nonetheless, to avoid confusion, it is advisable to keep the historical names based on the first findings. Type classification had been based on serology. In the past decade, however, new type numbers are being assigned to novel AdVs, the full genome sequence of which seems to warrant this. Consequently, HAdVs with type numbers above 52 do not necessarily represent distinct serotypes.

The emerging large quantity of data causes problems also by clearly demonstrating that we will find a very large number of instances of homologous recombination, especially in the case of the best studied human (or in general primate) AdVs. These recombinants have obviously a mixture of biological and genetic characteristics of the 'original' types.

The six clusters of AdVs, defined by gene organization and/or phylogenetic calculations, correspond to the five approved (*Mastadenovirus*, *Aviadenovirus*, *Atadenovirus*, *Siadenovirus*, *Ichtadenovirus*) and the pending sixth genus (*Testadenovirus*) (Fig. 1). The evolutionary distances among the AdVs seem to be generally proportional to those among the main lineages of their vertebrate hosts (in evolutionary order: fishes, turtles, squamates, birds, mammals) supporting the theory on the co-evolution of virus and host. However, there are a few exceptions when very distantly related viruses infect the same host, for example, bovine mastadenoviruses and atadenoviruses infect cattle, whereas the Sulawesi tortoise siadenovirus and testadenoviruses infect testudines (turtles). Obviously, besides co-evolution, several host switches also occurred. According to this hypothesis, the mastadenoviruses, aviadenoviruses, and testadenoviruses represent continuous co-evolving lineages, while squamate AdVs (atadenoviruses) have supposedly switched to ruminants, birds, and common tortoise. The host origin of the lineage of siadenoviruses is presently unknown. Representatives of this genus were found to infect birds, tortoises, and a frog. Similarly, the provenance of the white sturgeon AdV, the single member of the genus *Ichtadenovirus* is not clear either, as no other fish AdV was ever confirmed by targeted examinations or during the aquatic environmental metagenomics studies to date. By phylogenetic analyses, more recent host switches can also be recognized within the genera, for example from Old World monkeys and apes to humans, or from bats to dog-like carnivores, horse, and skunk.

Virion Structure

Adenovirus virions are non-enveloped, icosahedral particles 90 nm in diameter. The capsid consists of 240 nonvertex capsomers (called hexons), each 8–10 nm in diameter, and 12 vertex capsomers (penton bases), each with one or more (2–3) protruding antenna-like structures called fiber(s) 9–77.5 nm in length. The members of genus *Aviadenovirus* usually have two fibers per vertex. The number of fiber structures is not directly connected to the number of fiber genes. Fowl adenovirus 1 (FAdV-1), FAdV-4, and FAdV-10 even have two, tandem fiber genes of different lengths, resulting in two fibers of different sizes at each vertex. Members of species *Human mastadenovirus F* also have two fiber genes of different lengths, but the fiber structures are displayed separately on alternate vertices. Lizard adenovirus 2 (from Mexican bearded lizard) also has two fiber genes of different size. Three long fibers are displayed in some vertices while a single short fiber in the others. The major capsomers (hexons) are formed by the interaction of three identical polypeptides, designated as polypeptide II (the Roman numeral label is related to the relative mobility of structural proteins under reducing conditions in sodium dodecyl sulfate-polyacrylamide gel electrophoresis). Each hexon has two characteristic parts: a triangular top with three ‘towers’, and a pseudo-hexagonal base with a central cavity. Hexons, or more exactly their basal part, are packed tightly to form a protein shell that protects the inner components of the virion.

In members of the genus *Mastadenovirus*, polypeptide IX is located on the outer part of the capsid, keeping together the hexons in each facet (12 copies of protein IX per facet) (Fig. 2). In HAdVs, polypeptide IX also links two facets together across the icosahedral edge. However, polypeptide IX is not present in the members of any other genus. Two monomers of IIIa are located underneath the vertex region, and multiple copies of polypeptide VI are underneath the hexons. Penton bases are formed at the vertices by the interaction of five copies of polypeptide III, and are tightly associated with one, two or three fibers. Fibers are homotrimers of polypeptide IV, and have three structural domains, tail, shaft and the distal knob. There are six monomers of polypeptide VIII per facet: three of them wedged between polypeptide IIIa and the peripentonal hexons, and the other three around the icosahedral 3-fold symmetry axis, contributing with polypeptide IX to the stabilization of the facet. The core consists of the DNA genome complexed with four polypeptides: V, VII, X, and a virus-coded terminal protein (TP). Polypeptide V is found only in mastadenoviruses. Atadenoviruses have two unique structural proteins: p32K and LH3. The major capsid protein, LH3 forms prominent ‘knobs’ on the surface of the atadenoviruses and is located in the same relative position among the hexon subunits as protein IX in the mastadenovirus but sits on top of the central hexon trimers (probably holding the outer capsid together). A virus-coded protease is also packaged bound to the genome.

Adenoviruses are stable on storage in the frozen state. They are insensitive to lipid solvents. Heat sensitivity varies among the genera.

Genome

The adenovirus genome is a single linear molecule of double-stranded DNA (24,630–48,395 bp) containing inverted terminal repeats (ITR) of 26–721 bp at its termini. The 5′ ends of each DNA strand are linked covalently to the TP. The range of nucleotide composition is 33.24%–66.92% G + C. The genetic organization of the central part of the genome is conserved throughout the family, whereas the distal parts show large variations in length and gene content (Fig. 3).

Splicing was first discovered in AdVs, and is a common means of expressing mRNAs in this virus family. In the conserved region, most of late genes are expressed by splicing from the rightward-oriented major late promoter, located in overlap with the DNA-dependent DNA polymerase (pol) gene. The early genes encoding pol, the precursor of TP (pTP), and the DNA-binding protein (DBP) are expressed by splicing from leftward-oriented promoters.

Life Cycle

Replication of various human adenoviruses has been studied in detail, in particular with HAdV-2. Virus entry takes place via interactions of the fiber knob with specific receptors (most often the coxsackievirus and adenovirus receptor or CAR) on the surface of a susceptible cell followed by internalization via interactions between the penton base and cellular α_v integrins. Protein VI mediates the release of virions from the endosomes, allowing dynein-mediated transport on microtubules to nuclear pores. After uncoating, the virus core is delivered to the nucleus, i.e., the site of virus transcription, DNA replication and assembly. Virus infection mediates the shutdown of host DNA synthesis and later RNA and protein synthesis. Transcription of the AdV genome by host RNA polymerase II involves both DNA strands of the genome and initiates (in HAdV-2) from five early (E1A, E1B, E2, E3, and E4), two intermediate (IX and IVa2), the major late (L) and the U exon protein (UXP) promoters. All primary transcripts are capped and polyadenylated, with complex splicing patterns producing families of mRNAs. In primate adenoviruses, there are one

Fig. 1 Phylogenetic tree of adenoviruses based on maximum likelihood analysis of DNA-dependent DNA polymerase (pol) amino acid sequences from adenoviruses one from each species and pending species, or distinct strain with full pol sequence known. Multiple alignment: MultAlin; model selection: ProtTest 2.4; maximum likelihood calculation: PhyML 3.1 with model LG + I + G and Shimodaira-Hasegawa-like branch test for statistical test for branch support on the platform of Galaxy/Pasteur. Unrooted calculation; white sturgeon AdV-1 and slider AdV-1 are selected as outgroup for visualization. From the name of the adenovirus types the word ‘adenovirus/AdV’ was removed for clarity. In case of the common names of ‘psittacine AdV’ and ‘simian AdV’, the original hosts are shown in brackets. Adenovirus species are indicated. The bar indicates 20% difference between two neighboring sequences. SH (Shimodaira-Hasegawa) branch support values shown at the nodes.

Fig. 2 Stylized section of a mastadenovirus particle. Capsid proteins (II, III, IIIa, IV, VI, VIII and IX) and core proteins (V, VII, X and terminal protein /TP/) are labeled by Roman numbers related to the relative mobility of structural proteins under reducing conditions in sodium dodecyl sulfate-polyacrylamide gel electrophoresis). Protein V and IX (in red squares) occur only in mastadenoviruses. Instead of protein IX, a structural protein called LH3 can be found in almost all adenoviruses. As the structure of the nucleoprotein core has not been established, the polypeptides associated with the DNA are shown in hypothetical locations. Adapted from Harrach, B., Benkő, M., Both, G.W., *et al.*, 2011. Family *Adenoviridae*, In: King, A.M.Q., Adams, M.J., Carstens, E.B., Lefkowitz, E.J. (Eds.), *Virus Taxonomy: Classification and Nomenclature of Viruses*. Ninth Report of the International Committee on Taxonomy of Viruses. San Diego, CA: Elsevier, pp. 125–141.

or two virus-associated (VA) RNA genes. These are transcribed by cellular RNA polymerase III and facilitate translation of late mRNAs and block the cellular interferon response. In non-primate mastadenoviruses, no VA RNA genes could be identified. A non-homologous VA RNA gene has been mapped in some aviadenoviruses near the right end of the genome. The replication of aviadenoviruses has been shown to involve significantly different pathways from those characterized in HAdVs. This is not unexpected, given the considerable differences in gene layout between the non-conserved regions of the genome.

About 40 different polypeptides (the largest number being in aviadenoviruses and ichtadenovirus, the smallest in siadenoviruses) are produced. Almost a third of these compose the virion, including a virus-encoded cysteine protease, which processes a number of precursor proteins (these are prefixed with p). With the exception of polypeptides V and IX, the other structural proteins found in mastadenoviruses are conserved in every genus. Products of the four early regions of mastadenoviruses modulate the host cell's transcriptional machinery (E1 and E4), assemble the virus DNA replication complex (E2), and subvert host defense mechanisms (E3). The E2 region (encoding DBP, pol, and pTP) is well conserved throughout the family, while the E3 and E4 regions show great variation in length and gene content even among the mastadenoviruses. E1A, E1B 19K, and the E3 and E4 regions (with the exception of 34K, called ORF6 in HAdVs) occur only in mastadenoviruses. Genes encoding proteins related to 34K are also present in adenoviruses, usually in duplicate. Intermediate (IX, only in mastadenoviruses, and IVa2) and late gene products (in many mastadenoviruses expressed from five transcription units, L1–L5) are concerned with assembly and maturation of the virion. Late proteins include 52K (scaffolding protein) and pIIIa (L1); III (penton base), pVII (major core protein), V (minor core protein, only in mastadenoviruses) and pX (L2); pVI, hexon (II), and protease (L3); 100K, 33K (and its unspliced version, 22K), and pVIII (L4); and fiber (IV) (L5). Seemingly, there are no lipids in adenovirus particles. However, the fiber proteins and some of the nonstructural proteins are glycosylated.

Epidemiology

Adenoviruses are abundant and widespread and theoretically every reptilian, avian and mammalian species could host at least one AdV type. Endemic or enzootic infections that are frequently unapparent seem to be very common. In contrast, epidemic or epizootic occurrence is relatively rare but normally has much more significant consequences. The non-enveloped virions, shed by infected individuals, are rather stable in the environment and can preserve infectivity for long periods. The virions are not only able to tolerate adverse environmental effects, such as drought and moderate temperature or pH changes, but are also resistant to lipid solvents and simple disinfectants. There is evidence that HAdVs can persist and perhaps even retain infectivity in natural or communal water sources. Moreover, freshwater and marine bivalves have also been found to accumulate AdVs. Because of their

(Eds.), *Virus Taxonomy: Classification and Nomenclature of Viruses*. Ninth Report of the International Committee on Taxonomy of Viruses. San Diego, CA: Elsevier, pp. 125–141. with permission.

stability, AdVs have become a major indicator of viral pollution in the environment. Vertical transmission has also been documented in several host species, including birds and cattle.

Although different AdV types have different affinities for various organs and tissues, primary virus shedding is likely through the intestines. AdVs are often transmitted by person-to-person contact, particularly among young children where fecal–oral spread is also common. Aerosol transmission is probably not rare in crowded populations. Adenovirus DNA may be found in tonsillar tissue, peripheral blood lymphocytes, and lung epithelial cells long after clinical disease has abated. Swimming-pool-related outbreaks, particularly by strains causing keratoconjunctivitis or pharyngitis, are not uncommon. In poultry and other farm animals, transportation, crowding, and mixing of different populations can lead to mass infections accompanied by disease outbreaks.

Clinical Features

The tropism and pathogenicity of HAdVs are largely species- and type-dependent. Respiratory pathogens are common, although infections of a large variety of different organs have been described. The fiber protein mediates primary tissue tropism, and some of the specific determinants, epitopes, and receptors have been mapped. The most common clinical manifestations connected to members of each human AdV species are listed below. Members of *Human mastadenovirus B* are divided into two groups informally termed 'subspecies' HAdV-B1 and HAdV-B2 since they represent two phylogenetic lineages (Fig. 1).

HAdV-A

HAdV-12, HAdV-18, and HAdV-31 can replicate efficiently in the intestines, and, based on serological surveys, are common in the population, especially in children with gastrointestinal disease. However, their role in the etiology of infant diarrhea is yet to be determined. Serotypes belonging to this species are generally difficult to isolate and culture.

HAdV-B1

Respiratory pathogens HAdV-3, HAdV-7, HAdV-16, and HAdV-21 belong here (and HAdV-50). Seasonal outbreaks of febrile respiratory disease, mainly during winter, can be caused in infants by HAdV-7 in most parts of the world. Similar diseases, usually with a less severe outcome, can be seen among school children. In some countries, HAdV-3 is the dominant serotype, whereas HAdV-7 seems to have a number of different genotypes that shift occasionally in certain geographic areas. In addition to HAdV-7 and HAdV-21, HAdV-4 (species HAdV-E), and HAdV-14 (HAdV-B2) are most often implicated in the etiology of acute respiratory outbreaks among freshly enlisted military recruits in the USA.

HAdV-B2

HAdV-11, HAdV-34, and HAdV-35 cause persistent interstitial infection in the kidney and hemorrhagic cystitis. These HAdV types, along with HAdV-50, are most often shed in the feces or urine of acquired immune deficiency syndrome (AIDS) patients and organ or tissue transplantation recipients. Re-emergence of a genomic variant of HAdV-14 causing severe, sometimes fatal respiratory infections was reported first from the USA in 2006, later also detected in Europe and China.

HAdV-C

The low serotype designations (HAdV-1, HAdV-2, HAdV-5, and HAdV-6) of viruses in this species reflect the relative ubiquity of these viruses. These HAdVs can be isolated easily and, indeed, comprise approximately half of all HAdV serotypes reported to the World Health Organization. HAdV-1, HAdV-2, and HAdV-5 are known to maintain endemic infections, and most teenagers will have had infections with more than one serotype. The site of persistence is lymphoid tissue, and shedding can last for a couple of years after primary infection.

HAdV-D

This species contains 32 serotypes, and therefore encompasses well over one half of all known HAdVs. HAdV-8, HAdV-19, and HAdV-37 cause epidemic keratoconjunctivitis, especially in dry climates or densely populated areas. Other serotypes are rarely isolated except from immunocompromised patients. Virus shedding by asymptomatic healthy individuals was found to be common in Africa. Recently, by whole genome analysis, a large number of double or multiple HAdV-D intertypic recombinants, involved in epidemic keratoconjunctivitis, have been recognized. Several recombinant strains were assigned to novel type number (genotypes) without testing or confirming their serological distinctness.

HAdV-E

This species contains a single human serotype, namely HAdV-4, although different variants ('genotypes') of this virus have been described. HAdV-4 strains have been most often implicated in respiratory diseases among military recruits in the USA. The species encompass a number of novel isolates originating from chimpanzees and bonobos. In Japan, HAdV-4 is the second most important cause of adenovirus-associated eye disease after HAdV-8.

HAdV-F

The so-called enteric or fastidious HAdV-40 and HAdV-41 are classified here. The genetic distance between these two serotypes comes close to meriting separation into different species, but, for practical reasons, including indistinguishable pathology, they remain in a single species. These viruses are a major cause of infantile diarrhea all over the world. In Europe, a shift in dominance

from HAdV-40 in the 1970s to HAdV-41 after 1992 has been observed. Because of a deletion in the E1 region near the left end of the genome, HAdV-40 and HAdV-41 can be isolated and cultured only in complementing, transformed cell lines such as 293 or PER.C6.

HAdV-G

The most recently described HAdV serotype, HAdV-52, was recovered from a patient with diarrhea. No further cases or serologic evidence on the circulation of this virus have been reported yet. Interestingly, this species encompasses numerous monkey AdVs besides HAdV-52.

Epizootiology

Simian Adenoviruses

A series of simian viruses (termed SVs) were isolated from various tissue cultures prepared from apes and monkeys. These were numbered serially, irrespective of the virus family to which they belong, since identification and allocation to a family were performed later only. A considerable number of the SV isolates have been identified as adenoviruses. In many cases, unfortunately, the original SV numbers have been retained as the numbers of the AdV type, and thus a somewhat confusing system of SAdV numbering can still be encountered in publications, as well as in the records of the American Type Culture Collection. To date, there are > 55 simian adenovirus types (SAdV-1 through SAdV-55) and dozens of detected but not well characterized SAdVs. SAdV-1 to SAdV-20 originated from Old World monkeys, whereas SAdV-21 to SAdV-47, and further strains were isolated from apes (chimpanzees, bonobos, and gorillas). SAdV-48 to SAdV-55, and further variants are again from Old World monkeys. In the past years, novel adenoviruses have been described from New World monkeys. In one case, the possible transmission of the virus from diseased animals to the caretakers was also observed. Very recently, a dozen different prosimian AdVs were detected by PCR screening of samples directly from Madagascar and from zoos. Data concerning prevalence or pathogenicity of AdVs in their natural hosts are increasing continuously. An interesting mixing and grouping can be observed among the primate AdVs, suggesting that they can sometimes be less host specific and supposedly able to infect individuals of closely related host species.

Canine and Other Carnivoran Adenoviruses

For a long period, only canine AdVs had been known to infect carnivores. CAdV-1 is the causative agent of infectious canine hepatitis (Rubarth's disease), a life-threatening disease of puppies. Regular vaccination worldwide has decreased the number of clinical cases. Viruses, serologically indistinguishable from CAdV-1, have been found to cause encephalitis in foxes as well as infections in numerous other carnivorous animals including wolves, coyotes, jackals, otters, raccoons, and even bears. The disease caused by a genetically closely related virus, CAdV-2, is called kennel cough and is common among dog breeder stocks. There exist a couple of publications reporting cases of inclusion-body-hepatitis-like condition in felids. Yet, focused attempts to find a distinct feline adenovirus yielded only a single case of cat AdV amplification and partial sequencing from paraffin embedded sample. It is likely, however, that cats living in close proximity with humans can harbor HAdV-1 or HAdV-5 from species HAdV-C. More recently, specific adenoviruses have been described from hosts, namely seals and several sea lions, belonging to the superfamily of pinnipeds. Similarly, a distinct AdV had been found in polar bears died in zoos. Phylogeny inference and genome analyses imply that the AdVs isolated from, or detected in, some carnivorous animals (CAdV-1, CAdV-2, skunk AdV-1) have a close common ancestor with the AdVs discovered in different bats recently. This would explain the elevated pathogenicity of these AdVs in the newly invaded hosts. Indeed, skunk AdV was discovered from independent deadly diseases of pet African hedgehogs in Japan and the USA, in a marmoset in a Hungarian zoo and in North American porcupines.

Porcine Adenoviruses

At least five porcine adenovirus types (PAdV-1 to PAdV-5) are recognized. These represent three different species. Species *Porcine mastadenovirus A* contains three serotypes (PAdV-1 to PAdV-3) that are fairly similar to each other and cause no specific diseases. PAdV-4 (in species PAdV-B) has been described as associated with neurological disease, whereas PAdV-5 (in species PAdV-C) is more distantly related to PAdV-A. The pathogenic roles of porcine adenoviruses need further investigation.

Equine Adenoviruses

Two equine adenovirus serotypes (EAdV-1 and EAdV-2) have been isolated to date. EAdV-1 seems to be more prevalent and causes clinical respiratory diseases. It seems to be genetically close to certain bat AdVs so that a host switch has been suspected. On

the other hand, EAdV-2 appears to be the AdV co-evolved with horses. It usually causes gastrointestinal infection with mild or self-limiting disease in foals. Certain Arabian horse lineages carry a genetic defect that, when present in the homozygous state, results in severe combined immunodeficiency disease. Affected animals are incapable of mounting an immune response, and foals often die of pneumonia due to equine adenovirus infection, which would be generally harmless in immunocompetent individuals.

Bovine, Ovine, Caprine, and Other Ruminant Adenoviruses

Ruminant animals can harbor rather diverse AdVs. Several isolates originating from cattle, sheep, goat and deer species belong to various species in the genus *Mastadenovirus*. Unusual BAdVs, substantially differing from mastadenoviruses, as judged for example by the absence of the genus-specific antigen, were described four decades ago. These BAdV serotypes are now classified in a separate genus, *Atadenovirus*. One ovine (OAdV-7), one goat (GAdV-1), and one deer adenovirus (Odocoileus AdV-1) also belong here.

Bovine mastadenoviruses were recognized early on and were found occasionally to cause enzootic bronchopneumonia or calf pneumo-enteritis. However, experimental infection of young calves with the isolated adenovirus seldom, if at all, resulted in reproduction of disease. The early isolates of BAdV-10 originated from diseased or dead animals. In phylogeny reconstructions, BAdV-10 represents an independent lineage. It also has a very simple E3 region and a variable fiber gene. Therefore, it has been proposed to be in the process of switching from one host to another. Crossing the host barrier has also been suggested for BAdV-2, with two subtypes, each infecting cattle and sheep, respectively. Based on evolutionary relationships, BAdV-2 is presently classified into species *Ovine mastadenovirus A* together with serotypes OAdV-2 to OAdV-5. The newest isolated OAdV type is mastadenovirus OAdV-8.

The atadenovirus *Odocoileus AdV-1* caused hemorrhagic epizooty killing thousands of mule deer in California.

Avian Adenoviruses

Birds are known to harbor AdVs from three different genera.

In addition to the host origin, members of the genus *Aviadenovirus* can be distinguished from mastadenoviruses by the lack of the genus-common complement-fixing antigen. Twelve aviadenovirus serotypes have been described from chicken. A specific condition, referred to as hydropericardium syndrome, has been clearly associated with fowl adenovirus 4 (FAdV-4) from species *Fowl aviadenovirus C*. It occurs mainly in Asia causing great economical losses. Another specific disease the so-called gizzard erosion is caused by FAdV-1 (species FAdV-A). Infection with at least ten additional FAdV types may cause inclusion body hepatitis in chicken.

Novel aviadenoviruses have been isolated from, or detected by PCR and sequencing in, numerous host species including falcons, finches, gulls, parrots, pigeon, neotropic cormorant, Pacific black duck, and in unpublished cases from many other wild birds (Table 1).

The genus *Atadenovirus* contains duck adenovirus 1 (DAdV-1), the causative agent of the so-called egg drop syndrome (EDS) of chickens. The disease, causing dramatic decrease in the egg production of laying flocks, was first experienced in Europe in 1976 then soon became known worldwide. Retrospective serological studies confirmed the presence of hemagglutination inhibitory antibodies to EDS virus in archive serum samples originating from a large number of wild and domestic bird species, with predominance in waterfowl, which are now considered as the main reservoir. The presence of novel atadenoviruses has been reported in parrots, songbirds, chimney swift, finches, robin and tropical screech owl (Table 1). Additional yet unpublished atadenoviruses have been detected in various wild birds.

Another poultry pathogen, namely turkey adenovirus 3 (TAdV-3), is classified into the genus *Siadenovirus*. The distinctness of this virus, also known as turkey hemorrhagic enteritis virus, has been recognized early based on the lack of common cross-reacting antigen with aviadenoviruses or DAdV-1. Serologically indistinguishable strains have been associated with various pathological entities in turkey, pheasant, and chicken. Besides TAdV-3, the genus *Siadenovirus* encompasses the single known adenovirus from an amphibian host, frog adenovirus 1 (FrAdV-1). Recently, numerous novel siadenoviruses have been demonstrated by PCR and sequencing in different diseased or dead birds, including finches, parrots, pigeons, owls and a hawk, as well as penguins and skuas from the Antarctica. Psittacine AdV-2 seems to have high pathogenicity and is capable of crossing the species barrier. It has been detected in representatives of more than seven different species belonging to psittaciformes.

Reptilian Adenoviruses

Adenovirus infections in various snake and lizard species are reported frequently, but the number of virus isolates is still limited. In Germany, captive boid snakes, from different collections and breeders, seem to be infected by the same type of AdV, and also by a parvovirus (snake adeno-associated virus). Bearded dragons, a reptile pet of growing popularity, have a specific adenoviral infection and disease often manifesting in neurological signs, the so-called 'star-gazing'. The AdVs found in squamate reptiles, belong to genus *Atadenovirus*, and at least 25 distinct atadenovirus types, detected by PCR and sequencing, have been reported. An unusual virion morphology with triple fiber projection per vertices was discovered during the characterization of an AdV isolate

from Mexican bearded lizard. This virus was also found to have two fiber genes, a trait that usually broadens the host-cell range during infection.

In a dead specimen of the common (Greek) tortoise an adenovirus was detected supposedly as a result of host switching.

Most recently, novel AdVs representing a thus far unknown lineage, proposed as an additional genus (Testadenovirus), have been reported from testudines, including red-eared slider, yellow-bellied slider, box turtle, eastern box turtle, pancake tortoise, and red-footed tortoise.

An interesting case of siadenovirus infection in confiscated Sulawesi tortoises has been described. Significant fatalities and transmission of this virus to other turtles has also been reported. The pathogenic role of the adenoviral infections in reptiles needs further studies nonetheless the introduction of the practice of quarantining is highly recommended.

Frog and Fish Adenoviruses

Data concerning adenovirus infection of aquatic vertebrates are scarce. In fact, only a single AdV has been isolated from each of the two host classes, amphibians and fish. Interestingly, the frog AdV was isolated from a renal tumor of a leopard frog on a reptilian cell line (TH1) prepared from turtle heart tissue. FrAdV-1 has a genome organization similar to that of TAdV-3, and the common evolutionary origin of these two viruses in genus *Siadenovirus* is supported by phylogenetic calculations. The only adenovirus isolate available from fish was obtained from a healthy adult specimen of an ancient Chondrostei species, the white sturgeon. Experimental transmission of the virus failed to produce any clinical signs. Genomic characterization of the sturgeon adenovirus implied the need for creating a new genus, *Ichtadenovirus*. Nuclear inclusion bodies typical of adenoviruses and adenovirus-like particles have been observed by light and electron microscopy, respectively, in damaged tissues of a couple of sea fish species, but molecular confirmation of AdV infection has not been successful. Some of these suspected viruses turned out to have genes similar to those in polyomavirus, but having larger and different genomes thus being candidate for members of a new family, still to be proposed officially (Adomaviridae).

Pathogenesis

Adenovirus infections of man generally occur in childhood, and the outcome varies in severity from asymptomatic to explosive outbreaks of upper or lower respiratory tract manifestations. Less commonly, AdVs cause gastrointestinal, ophthalmic, urinary, and neurological diseases. The vast majority of adenovirus-caused diseases are self-limiting. However, immunocompromised patients, above all organ transplant recipients, individuals infected with human immunodeficiency virus and developing AIDS, and those receiving radiation and chemotherapy against tumors, represent special populations that are prone to experience grave, frequently fatal consequences of AdV infection. In numerous cases, the organ to be transplanted itself proves to be the source of invasive AdVs. Sporadic fatal infections may occasionally occur in healthy, immunocompetent individuals. In such cases, the presence of certain predisposing immunogenetic factors cannot be excluded. Cellular immune responses are also important for the recovery from acute adenovirus infection. Peripheral blood mononuclear cells have been found to exhibit proliferative responses to HAdV-2 antigen. This function is mediated by CD4⁺ T cells, which seem to recognize conserved antigens among different HAdV serotypes.

The incubation period from infection to clinical signs is estimated to be 1–7 days and may be dose dependent. Clinical symptoms during the initial viremia are dominated by fever and general malaise. Recovery from infection is associated with the development of serotype-specific neutralizing antibodies that protect against disease or reinfection with the same serotype.

Pathology by AdVs is partially the consequence of viral replication and cell lysis. Correspondingly, in various tissues and organs, such as bronchial epithelium, liver, kidney, and spleen, disseminated necrotic foci can be observed upon necropsy and histopathological examination. Characteristic intranuclear inclusion bodies and so-called smudge cells contain large amounts of adenovirus capsid proteins. Besides the lesions caused by virus replication, direct toxic effects of high doses of structural proteins, as well as the host's inflammatory response, may contribute to the aggravation of pathology.

Experimental infection of animals with various AdV types seldom results in pathology similar to that experienced with the same virus under natural circumstances. One of the few exceptions is turkey hemorrhagic enteritis, the pathogenesis of which has been studied in detail. TAdV-3 causes intestinal hemorrhages and immunosuppression. By in situ DNA hybridization and PCR, the presence of TAdV-3-specific DNA as evidence for virus replication has been demonstrated in the immunoglobulin M-bearing B lymphocytes and macrophage-like cells, but not in CD4⁺ or CD8⁺ T lymphocytes. Interestingly, fewer virions were present in the intestines, which are the principal site of pathology, than in the neighboring lymphoid organs including spleen and cecal tonsils. This finding strongly suggests that the intestinal lesions induced by TAdV-3 are mediated by the immune system. Systemic or intestinal hemorrhagic disease of ruminants seems to be related to virus replication in endothelial cells.

Diagnosis

With the development of modern techniques, especially PCR and direct DNA sequencing, the number of AdVs detected in various organ samples of human or animal origin has increased rapidly. However, there is no official agreement or convention on the

criteria that would be prerequisites for the approval of new AdV types. The conventional methods, including virus isolation in tissue culture, raising antisera, and performing a large set of cross-neutralization tests, are cumbersome, and the majority of medical and veterinary diagnostic laboratories do not possess appropriate prototype strain and serum collections. Full genomic sequences should validate new types even in the absence of isolated virus strains. However, the value of short sequences from PCR fragments is still a topic of debate. In principle, PCR and sequencing should be able to replace serotyping if appropriate targets are identified.

Human medical laboratories use commercially available tests, such as complement fixation and enzyme immunoassay, to detect adenovirus-specific antibodies that cross-react with all serotypes. Nearly all adults have serologic evidence of past infection with one or more AdV types. For the detection of viral DNA by PCR, the most common target was initially the gene encoding the major capsid protein, the hexon. With subsequent restriction enzyme digestion, typing systems for HAdVs and FAdVs have also been elaborated. Recently, a nested PCR method, targeting the most conserved part of the adenovirus-coded DNA-dependent DNA polymerase gene, became very popular. The highly degenerate consensus primers seem to be capable of facilitating amplification of DNA from every adenovirus, irrespective of its genus affiliation.

Treatment

No specific anti-adenovirus therapy has yet been established. Recent advances in understanding the pathophysiology of fulminant adenovirus diseases in immunocompromised patients have prompted the consideration of applying donor lymphocyte infusions after transplantation.

Cidofovir is a monophosphate nucleotide analog that, after undergoing cellular phosphorylation, competitively inhibits incorporation of dCTP into virus DNA by the viral DNA polymerase. Incorporation of the compound disrupts further chain elongation. Efforts to improve its effect are in progress. There are a growing number of positive experiences with using this drug to combat adenovirus infections.

Successful disinfection of poultry houses and stables can be performed with the use of chlorine-releasing agents, iodophors or quaternary ammonium compounds.

Prevention

In the USA, orally administrable, live, enteric-coated vaccines against HAdV-4, HAdV-7, and HAdV-21 were used in military units for a couple of decades. The vaccine went out of production in 1996 and the supplies were exhausted by 1999. Soon, re-emergence of HAdV-7 and especially HAdV-4 was verified and about 12% of all recruits were affected by adenovirus disease. The vaccination program, restored at the military in October 2011, caused a prompt 75% reduction in the incidence of febrile respiratory illness among the new trainees.

In the veterinary practice, dog vaccination schedules all over the world invariably include a live or killed CAdV-2 component against infectious canine hepatitis. Inactivated vaccine for horses against equine adenoviruses has been prepared in Australia. In farm animals, inactivated bivalent vaccines (containing one mastadenovirus and one atadenovirus BAdV type) have been in use in several countries for controlling enzootic calf pneumonia or pneumo-enteritis. In poultry practice, commercially available or experimental vaccines for the prevention of EDS or turkey hemorrhagic enteritis are applied occasionally. There are several attempts ongoing for the production of recombinant subunit vaccines, which should be safer than vaccines derived from tissue culture or the organs of infected birds.

Adenoviruses as Vectors

HAdV-5 has been engineered and used most extensively as a gene delivery vector with a view to applications in gene therapy, immunization and antitumor medicine. Other human adenoviruses such as HAdV-3, -4, -26, -35, -41, -48, -49, etc. (either replication-competent or replication-deficient) or even nonhuman serotypes (OAdV-7, CAdV-2, chimpanzee and rhesus monkey AdVs), are being tested as a means of overcoming the problem posed by preexisting neutralizing antibodies in the human population, and also to achieve targeting to specific organs and tissues. Bovine, porcine, canine, and fowl AdV types have also been tested as novel antigen delivery vectors for immunizing animals of the respective species.

African Horse Sickness Virus (*Reoviridae*)

Piet A van Rijn, Wageningen Bioveterinary Research, Lelystad, The Netherlands and North-West University, Potchefstroom, South Africa

© 2021 Elsevier Ltd. All rights reserved.

Classification

African horse sickness virus (AHSV) is a virus species within the genus *Orbivirus* belonging to the subfamily Sedoreovirinae within the *Reoviridae* family. Other orbivirus species are equine encephalosis virus, also infecting horses, and bluetongue virus (BTV) and epizootic hemorrhagic disease virus (EHDV) both infecting instead ruminants. AHSV causes African Horse Sickness (AHS), which is a notifiable disease according to the World Organization of Animal Health (OIE). BTV is the prototype orbivirus and shares morphology and many molecular and virological properties with AHSV. Nine serotypes of AHSV have been recognized.

Virion Structure and Genome

AHSV is a non-enveloped virus of 70–80 nm in diameter with an icosahedral structure. The viral genome of double-stranded (ds) RNA is about 19 kb in total and fragmented in ten genome segments (Seg-1 to Seg-10) varying in length from 0.8 to 3.9 kb. The segmented genome encodes seven structural proteins VP1–VP7 and at least four non-structural proteins NS1, NS2, NS3/NS3a, and NS4. Structural proteins VP2, 3, 5 and 7 form a three-layered virus particle harboring enzymatic proteins VP1, VP4 and VP6 in addition to one copy of each dsRNA genome segment. The inner protein layer consists of 120 VP3 molecules. VP3 displays two conformations in dimers and are clustered around a five-fold axis and form a replication complex together with the enzymatic proteins while VP3 decamers forms a subcore particle in an orbicular configuration. The subcore forms the core particle by a layer of 780 copies of VP7. A third protein layer, which is the outer shell, consists of VP2 and VP5 and determines the serotype of the infectious virus particle. Serotypes have been recognized by specific neutralizing antibodies and reflect genetic differences observed in Seg-2, which encode serotype dominant VP2. Serotypes 1 and 2, 3 and 7, and 5 and 8 induce some cross-neutralizing antibodies and display a higher percentage of genetic homology between each other compared to other serotypes. Non-structural proteins are not part of the virus particle but are expressed in the infected cells and support virus replication.

Life Cycle

AHSV infects cells of the insect vector as well as of the mammalian host. After entering the cell, the outer shell is removed and the uncoated virus, the core particle, is released in the cytoplasm. Messenger RNAs (mRNAs) are synthesized inside the transcriptionally active core particle from all ten dsRNA genome segments and secreted into the cytoplasm. In this way, the viral genome is not exposed to cellular defense mechanisms triggered by dsRNA. Translation of viral mRNAs is specifically enhanced by the NS1 protein. Later after infection, mRNAs are recruited from the cytoplasm into replication complexes in virus inclusion bodies (VIBs) formed by the NS2 protein. Pre-subcore particles are formed within VIB, and initiate the replication of recruited single-stranded RNAs into dsRNA genome segments. The mechanism by which exactly one copy of each RNA segment is recruited into one virus particle is not completely understood but likely occurs according to a “follow-the-leader” process initiated by specific intersegmental RNA-RNA interactions and macromolecule interactions. After formation of core particles and assembly of the outer shell in a late stage, the progeny virus is released from the infected cell through an NS3/NS3a mediated process using cellular transport mechanisms and/or by budding on the cell membrane causing a cytopathogenic effect (CPE). Virus release from culicoides cells is dependent on NS3/NS3a protein and indeed infected culicoides cells show no CPE.

In order to complete its life cycle, replication and transmission of AHSV between equines and midges are crucial. Midges are infected by feeding on viremic equines. Saliva, gut components, viral proteins, virus dose, and likely the gut microbiome influence AHSV infection of gut cells. Progeny virus is released into the hemolymph and, after dissemination throughout the midge, several organs are infected. Infection of salivary glands leads to virus release into saliva and transmission of AHSV to susceptible equines by every next blood meal. The interplay between virus and midge is very specific, since only a very few culicoides species are competent midges able to transmit AHSV to susceptible animals. Saliva, as well as trauma by bites, presumably enhance the infection of the equine host. In conclusion, the life cycle of AHSV requires replication in both the competent midge and susceptible equine hosts and at least two subsequent blood feedings by competent midges on equines.

Epidemiology

AHS is an arthropod-borne noncontagious disease of *Equidae*. AHS is endemic in tropical sub-Saharan Africa where one or more serotypes at any given time are circulating asymptotically in zebra and the African donkey. In subtropical regions,

AHS displays a seasonal occurrence with the first cases appearing in late summer while the disease declines or even disappears in the autumn due to lower temperatures and the reduced midge population. Occasionally, the affected areas can expand by changes of climate and environmental conditions. In the past, AHS outbreaks have also been reported outside Africa in the South-East Asia and the Iberian Peninsula. Local spread of AHS is always associated with the presence of competent infected biting midges spreading by wind and active flight. The most relevant competent midges for AHSV in Africa are *Culicoides imicola* and *Culicoides bolitinos*. Usually, midges become persistently infected and are lifelong virus source for onward transmission. In contrast, susceptible equine hosts are thought to be infectious only temporarily. African wildlife is an important AHSV reservoir. For example, infected zebra can be viremic for up to 40 days as opposed to domestic horses, if they survive the infection, are usually viremic for 2–3 weeks. Movement of viremic equines over long distances can lead to new epidemics but these depend on the presence of local competent midges for onward transmission. For instance, the last recorded European AHS epidemic occurred in Spain (in 1987–90) and was caused by the transmission of AHSV to local horses by indigenous *Culicoides imicola* which fed on imported viremic zebra. In the 21st century, the distribution of several midge-borne orbiviruses and their vectors has been dramatically expanding both to the south and north in different parts of the world. Presumably, climate change and globalization will further expand habitats of potential competent midges. *Culicoides sonorensis* in the Americas and *Culicoides brevitarsis* in Australia are known BTV transmitters but their vector competence for AHSV is unknown. The largest recorded Bluetongue outbreak in Europe in 2006–2009 was unexpectedly spread by indigenous midge species belonging to the *Culicoides obsoletus* group. Accordingly, the epidemiology of AHS could drastically change in the future and might include introduction and expansion of the disease to historically AHS-free regions with a moderate climate.

Clinical Features

The incubation period in horses after natural AHSV infection is 5–9 days, whereas after experimental infection the incubation period is in general 3 days but depends on the dose and route of virus infection. The prognosis for infected horses is extremely poor as the mortality rate is 70%–95%. The fatality rate for African donkeys and zebra is very low (5% to 10%), whereas approximately 50% of infected mules will survive AHSV infection. There are four classical clinical forms of AHS in equines. The peracute, pulmonary form occurs in fully susceptible animals and has a short course. Infected horses with this form will rarely recover. The rise in body temperature starts after 3–5 days and can reach 40–41°C. This disease form is marked by rapidly progressive respiratory failure leading to a higher breathing frequency and further supported by abdominal heave lines. The horse appears exhausted and can stand with the forelimbs spread with an extended head and neck, profuse sweating, and dilated nostrils. Uncontrollable coughing with frothy, serofibrinous fluid exuding from the nostrils is common in the terminal stage of the disease. The respiratory distress usually starts suddenly a few hours before death. The subacute, cardiac, edematous form starts with rising in body temperature to 39–41°C about 7 days after infection and lasts in general for a couple of days. The fatality rate of this form is about 50%. The head may show severe swelling, including eyelids, lips, cheeks, tongue, intermandibular space, and laryngeal region. A characteristic symptom of this form is the swelling of the supraorbital fossae that may include conjunctival swelling with petechiae. The swellings may extend to the neck down to the chest. Remarkably, ventral edema and edema of the lower limbs are not seen. Paralysis of the esophagus may result in aspiration pneumonia and sublingual hemorrhages. The horse becomes very depressed and may lie down frequently for short periods. In the end, the horse dies by heart failure in about two weeks after onset of clinical signs. Horses that recover show gradually reducing swellings. The most commonly observed mixed, acute form displays signs of both the pulmonary and edematous forms with mortality rates around 70%. Mostly, signs are observed at post-mortem examination of fatal cases. Mild pulmonary signs seem to be not progressive, whereas edematous swellings and fluid in the body cavities seem to result in heart failure and death. Still, other typical signs of the pulmonary form are also observed in cases of the mixed form. The fourth form is horse sickness fever, which is the mildest form of the disease and is often missed. The incubation period is long (9 days) and the rise in body temperature can slowly reach 40°C. Clinical signs are not obvious. This mild form is usually seen in resistant or partially protected equines such as zebra, donkeys, or previously vaccinated horses. Horses that recover from natural AHSV infection develop lifelong immunity for the respective serotype and partial protection against closest related serotypes. Foals of immune mares show passive immunity for 3–6 months depending on the amount of AHSV directed antibodies received by uptake of colostrum.

Pathology

The pulmonary form shows the most characteristic post-mortem changes such as edema of the lungs resulting in foam production in the air pipe and bronchia and hydrothorax (Fig. 1).

Extensive alveolar edema and particolored hyperemia of the lungs are seen in peracute cases, whereas extensive interstitial edema is observed for more prolonged courses. The lungs may appear reasonably normal, but hydrothorax is common and the thoracic cavity may contain several liters of fluid. Less frequent are periaortic and peritracheal edematous infiltration. Cardiac lesions are not obvious, but epicardial and endocardial petechial hemorrhages are sometimes observed. Particularly, the lymph nodes in the thoracic and abdominal cavities are edematous and enlarged. Regarding the gastrointestinal tract, hyperemia of the

Fig. 1 Severe characteristic post-mortem observations in a horse which died as a result of AHSV infection. (A). Hydrothorax. (B). Formation of foam in the air pipe and bronchia.

glandular fundus of the stomach, hyperemia and petechial hemorrhages in the mucosa and serosa of the small and large intestines, subcapsular hemorrhages in the spleen, and congestion in the renal cortex are reported. The cardiac form typically shows yellow, gelatinous infiltration in the subcutaneous and intermuscular fascia, primarily of the head, neck, and shoulders. Infrequently, lesions may be observed in the chest, ventral abdomen, and rump. Hydropericardium is common, with extensive petechial and ecchymotic hemorrhages on the epicardium and endocardium. In contrast to the pulmonary form, lung edema is not present or very mild, and hydrothorax is rare. In addition to those found for the pulmonary form, submucosal edema of the cecum, large colon, and rectum is more pronounced. The mixed, acute form of the disease shows a combination of those found in the pulmonary and cardiac forms.

Diagnosis

Clinical diagnosis is not very specific especially in the early phase of AHS. However, additional factors support a presumptive diagnosis, such as other AHS suspicions or lethal confirmed AHS cases in the vicinity of the suspected horse. In a later phase of the disease, once characteristic clinical signs typical for AHS develop, differentiation from other equine diseases also improves clinical diagnosis. Specific findings by post-mortem examination further increase the differential diagnosis. AHS can spread very rapidly and causes huge economic and enormous socio-emotional impact by its severity. Therefore, AHS is a notifiable disease according to the World Organization of Animal Health (OIE). Any suspicion of AHS must be promptly reported to national veterinary authorities. The suspected horses should be correctly diagnosed with laboratory diagnostics as soon as possible in order to quickly install effective, feasible, and acceptable control measures. Further, the suspected horse must be protected against bites of midges to prevent further spread of disease by housing and use of horse blankets, repellents, and/or insecticides. The veterinary authority

will advise in this and further arrange and submit blood samples to an authorized laboratory, often the national reference laboratory for AHS. Preferably, all sick and healthy equines on the premises should be blood sampled. In the case of deceased horses, samples of spleen, lung lymph nodes and samples of any other organs with obvious pathology should be collected too, refrigerated and transported on ice for diagnostic purposes. Many highly sensitive and specific laboratory diagnostic tools for AHS have been developed and are operational in authorized laboratories to quickly confirm or exclude AHSV infection. Real-time reverse transcriptase polymerase chain reaction (PCR) assays for AHSV have been developed and are operational in diagnostic laboratories as first-line diagnostic tool. Several genome segments have been targeted which also opens the possibility for confirmatory PCR assays. Confirmation could be also performed with Seg-2 based PCR assays in order to identify the virus serotype. The latter can be supportive to find the original virus source, and is important in case vaccination against the spreading of a specific AHSV serotype is considered. In addition, virus isolation is performed to further characterize and investigate the causing virus, including serotyping with virus neutralization tests using reference sera against each of the nine serotypes. However, virus isolation is not routinely used for diagnostic purposes because this method is less sensitive, laborious and time-consuming. At one week after AHSV infection or later, antibodies against AHSV are detected by ELISA specific for VP7 antibodies and confirms AHSV infection. High throughput ELISAs are routinely used and are highly sensitive and specific detecting all nine AHSV serotypes. Neutralizing antibodies are detected later after infection with serum neutralization tests using nine reference strains of AHSV serotypes. Neutralizing antibodies are in majority serotype specific and directed to VP2.

Treatment, Control, and Prevention

There is no adequate treatment for AHS, and appropriate supportive therapy can be provided based on the observed clinical signs. AHSV infections must be detected and controlled as soon as possible. Importantly, control measures should prevent the spread of AHS to disease-free areas, countries or horse populations. Enforcing quarantine periods, mandatory protocols for clinical inspections and test procedures in combination with insect control measures prior to allowing import of equines are described for international equine transports over long distances. However, local expansion of an affected area is hard to stop due to local transport, movement of animals and, more importantly, spread by competent midges.

National authorities in AHS endemic, as well as in AHS-free countries, together with national reference laboratories, horse industries, owner organizations, and veterinary services have developed contingency plans describing control of AHS according to recommendations of OIE and WHO. In general terms, the suspected horse is temporarily contained with respect to access of midges, and official authorities must be informed. After confirmation by laboratory diagnosis, control measures as described in contingency plans are instantly implemented. Follow-up control measures regarding confirmed cases and (suspected) horses on the same premise are under debate and vary between national contingency plans. For example, infected and/or suspected horses are euthanized or receive supportive therapy while insect control strategies are undertaken. All contingency plans describe the installation of different zones: the affected zone around the affected holding (3 km diameter), surrounded by the protective zone (100 km diameter) and the surveillance zone of an additional 50 km radius around the protective zone. Actions are different for these zones and vary in different national contingency plans. Movement of equines from the affected zone is prohibited and is restricted or allowed in combination with negative test results, quarantine period and vector control measures for the other zones. The temporary or permanent housing of equines, removal of midge breeding places, and use of repellents, insecticides, and horse blankets are also described in contingency plans. Clinical inspections and surveillance are intensified in all zones. These control measures are adopted and specified to the local or national situation with regard to feasibility, such as the capacity of accommodation/stables, possibilities for insect control, the behavior of competent midges (if known), and the number of equine wildlife and domestic horses. Furthermore, contingency plans describe the possibility of vaccination in order to prevent disease and eventually eradicate AHS. In most cases, the decision by authorities to start vaccination campaigns in the affected area or country depends on the success of already undertaken actions, the feasibility, and of course, the availability of suitable AHS vaccine.

Vaccination is the most effective way to protect horses and to eradicate AHS outbreaks. Still, success by vaccination strongly depends on the profile (efficacy, safety, costs, acceptance) of the used vaccine. Currently, conventionally live-attenuated vaccines (LAV) are available for AHS in several African countries. Subsequent vaccinations with affordable cocktail vaccines for multiple serotypes protect horses against all nine serotypes. LAVs can, however, induce viremia and can spread to, and by, midges. Indeed, virulent variants (partially) derived from LAVs by reassortment events and/or by reversion to virulence have been reported. The Spanish AHS outbreak has been eradicated, first by use of LAV, and later by inactivated AHS vaccine which is more expensive but safer. Both vaccine types do not enable DIVA (differentiating infected from vaccinated individuals) and complicate eradication programs, and safe trade of equines is strongly hampered by this shortcoming.

Experimental vector- and subunit vaccines are completely safe and DIVA vaccines in combination with VP7 based ELISAs. Protection is mainly based on immune responses against outer shell proteins. Further, several virus-based vaccine platforms have been developed by genetic modification and applied for all nine serotypes by exchange of outer shell proteins. Consequently, virus-based vaccines induce full-blown immune responses against almost all viral proteins. Disabled infectious single cycle/cell (DISC) vaccine lacks essential protein VP6 and non-essential NS4. In effect, DISC vaccine is produced by *in trans* complementation on cells constitutively expressing VP6 protein. DISC vaccination leads to an abortive infection, since no progeny infectious virus can be produced in equines. AHSV without non-essential NS4 or NS3/NS3a are attenuated, protective and similarly produced as LAVs. AHSV without NS3/NS3a does not cause viremia and does not propagate in midges and is therefore named disabled

infectious single animal (DISA) vaccine. Furthermore, the DISA vaccine platform is DIVA compatible with the experimental NS3/NS3a based ELISA and a DIVA PCR test. All these experimental (vector) vaccine platforms, including easy-to-produce deletion mutants of AHSV, are very promising but are classified as genetically modified organisms and regulatory hurdles hamper their use at the moment. In conclusion, there is a desperate need for improved AHS vaccines in order to reduce the economic and socio-emotional impact caused by this devastating viral disease of horses.

VETfL Vaccinia virus early transcription factor

Glossary

Apoptosis A highly regulated form of programmed cell death.
Capsomers Capsomers are subunits of the capsid, an outer covering of protein that protects the virus genetic material.
Clathrin-mediated endocytosis A vesicular transport event that facilitates the internalization of molecules including receptors. This is involved in various processes including signal transduction, receptor recycling, virus entry. The process involves clathrin, a tri-skeleton shaped scaffold protein.
C-type lectin A type of carbohydrate-binding protein domain known as a lectin. The C-type lectin require calcium for binding. C-type lectin have diverse functions including regulation of cell adhesion, immune responses and apoptosis.
Entry fusion complex The entry fusion complex is a multi-component protein complex required for fusion of the virus envelope with cellular membranes to enable virus entry.
ERCC4-like nuclease An enzyme involved in DNA recombination or repair.
Genotypes This term is used to describe genetic variants of a given microorganism, in this case African swine fever virus.
Filopodia Slender cytoplasmic projections that contain actin filaments cross-linked into bundles by actin-binding proteins.

Guanyl transferase Three enzymes (RNA triphosphatase, guanyl transferase and methyl transferase) which are involved in the addition of the methylated 5' cap to mRNA.
Immunogold electron microscopy Immunogold labelling is a technique which involves binding of antibodies attached to gold particles to proteins. These complexes can then be detected by electron microscopy to localise specific proteins.
Macropinocytosis Is a form of uptake of materials including solutes from the extracellular fluid. The uptake mechanism is non-specific and taken advantage of by many pathogens. Once inside cells macropinosomes mature through endosomes.
Multigene families Multigene families are groups of genes from the same organism that encode proteins with similar sequences over all or part of the sequence.
Myristoylation Involves covalent attachment of a myristoyl group by an amide bond to an alpha amino group of an N-terminal glycine residue. Commonly this can act as a membrane anchor for proteins.
Sylvatic cycle The sylvatic cycle is the fraction of the pathogen population's lifespan spent cycling between wild animals and vectors.

African Swine Fever Virus

Classification

The *Asfarviridae* family consists of a single genus *Asfivirus* which contains one member: African swine fever virus (ASFV). The virus contains a double-stranded DNA genome varying in length between 170 and 193 kbp with terminal cross-links and inverted terminal

repeats. The predominantly cytoplasmic replication cycle and genome structure resembles that of the *Poxviridae* although the icosahedral capsid structure differs. African swine fever virus encodes enzymes and factors required for replication and transcription in the cytoplasm, in common with other large DNA virus families that have a replication stage in the cytoplasm. Genome sequencing has shown that ASFV is only distantly related to other viruses but shares the highest number of conserved genes with several viruses that infect amoeba, including Faustovirus, kaumoebavirus and Pacmanvirus. These giant viruses have genome sizes of greater than 400 kbp and share approximately 30 genes with ASFV including genes involved in replication, transcription and virus morphogenesis.

Virion Structure

ASFV has a multi-layered structure consisting of a nucleoprotein core, 70–100 nm in diameter, inside a protein core shell which is surrounded by an internal lipid layer (Fig. 1). The icosahedral capsid is assembled on this internal envelope. These intracellular mature particles are 170–190 nm in diameter and gain an additional membrane as they bud from the plasma membrane of the infected cell to form the extracellular enveloped virus that is 175–215 nm in diameter. Both the intracellular mature and extracellular enveloped forms of the virus are infectious. The capsid show icosahedral symmetry (T- 189–217) corresponding to 1892–2172 capsomers each observed as a hexagonal prism with a central hole. The distance between capsomers is 7.4–8.1 nm.

Mass spectrometry analysis of purified virus particles has identified 68 virus encoded proteins of which more than 20 have no known function. About 20 additional proteins in the virus particle were identified as host proteins. ASFV encodes for two polyproteins, pp220 (CP2475L) and pp62 (CP530R) which are proteolytically cleaved, by a virus-encoded cysteine protease (S273R). Mature peptide products of molecular weight 150, 37, 34, 14, and 5 kDa from pp20 and 35, 15, and 8 kDa from pp62 are incorporated into the core shell. The main virus capsid protein, p72 (B646L), represents about 10% of the mass of the virus particle. The p49 (B438L) protein is required for forming vertices of the capsid and is also present in the virus particle. Proteins present in the nucleoprotein core include a histone-like DNA binding protein A104R, components of the multi-subunit RNA polymerase and other enzymes and factors required for early transcription for example the mRNA capping and polyadenylation enzymes, early transcription factors and three helicases. Enzymes involved in the virus encoded DNA repair system are also packaged in the virus particle presumably in the core. Only one viral protein has conclusively been demonstrated to be in the external envelope, the type I membrane protein encoded by EP402R which contains an extracellular domain similar to host CD2

Fig. 1 African swine fever virus structure. Electron micrograph showing the Ba71v isolate of ASFV budding from a Vero cell with a cartoon highlighting the different structural elements. Known viral contents of the nucleoid, core shell, internal envelope, capsid and external envelope are indicated. The scale bar is 100 nm.

protein. The virus CD2 like protein (CD2v) is required for the binding of red blood cells to virus infected cells and extracellular virions. A number of membrane proteins are found on the internal virus envelope including p54 (pE183L), p22 (pKP177R), p17 (pD117L) and p12 (pO61R). The latter was previously shown to be involved in virus attachment. Several ASFV proteins have similarities to components of the vaccinia virus entry fusion complex and it is possible that a similar ASFV complex is localised to the internal envelope.

Virus particles band at 1.095 g/cm^{-3} in Percoll and $1.19\text{--}1.24 \text{ g/cm}^{-3}$ in CsCl. The S_{20W} is about 35,00S. Virus infectivity is stable over a wide pH range between 4 and 13 but is inactivated by treatment at 60°C for 30 min or by UV irradiation. Chemical treatment with some disinfectants, for example 1% formaldehyde, 2% NaOH or paraphenylphenolic compounds effectively inactivate virus.

Genome Organisation

The ASFV genome consists of linear double stranded DNA varying between 170 and 193 kbp depending on the isolate. The genome termini are covalently closed and consist of two flip-flop forms that are inverted and complementary to each other. Adjacent to the termini are tandem repeat arrays. Genome sequences present in sequence databases generally do not include all of the terminal repeat sequences or terminal crosslinks.

The ASFV genome consists of about 150–167 open reading frames (ORFs) which are closely spaced and read from both DNA strands as shown on Fig. 2. In some genome regions a number of consecutive ORFs are on the same DNA strand. Some of these genes are part of multigene families (MGFs) that have evolved on the virus genome by a process of gene duplication and in some examples transposition to the other end of the genome. The number of ORFs is based on the definition that the minimum size for an encoded protein is 60 amino acids and the ORFs do not overlap extensively with other major ORFs. Thus, some smaller ORFs may encode functional proteins but may have been missed from the current sequence annotations of the ASFV genome. Information from the transcript map of the ASFV genome may help in identification of any additional expressed small ORFs. The

Fig. 2 Genome of African swine fever virus. Schematic representation of the African swine fever virus Georgia 2007/1 isolate. Open reading frames are indicated by arrows indicating the direction that these are read.

intergenic region between ORFs is generally short and contains a short promoter sequence immediately upstream of the ORF. The virus encoded RNA polymerase and transcription factors bind to initiate transcription from the downstream ORF. These promoter sequences are generally AT rich and consensus promoter sequences for replication stage specific transcripts, (immediate early, early, intermediate, late) have not been identified.

Partial sequencing of the gene for the major capsid protein, p72/B646L, has been used to assign ASFV isolates to 24 different genotypes falling in three main clades. These were all found in East Africa, where the ancient sylvatic cycle is present. Genotypes that have spread more widely in domestic pigs include the genotype I in central and West Africa, genotype IX in Kenya and Uganda and genotype II in the Caucasus, Russian Federation, Europe and China. Gain or loss of members of multigene families (MGF) is the main mechanism for genome variability. Loss of some members of MGFs 360 and 505/530 (see below) have been associated with reduction in virulence for domestic pigs. In addition frame shift mutations have been identified in some genes, notably the genes coding for pEP402R/CD2v and the C-type lectin p153R in some low virulence virus isolates. The expression of pEP402R/CD2v protein is required to cause the binding of red blood cells to infected cells, a process referred to as haemadsorption. Thus virus isolates that do not express this protein do not cause haemadsorption.

The different functional classes of ASFV encoded proteins are indicated on the genome map in [Fig. 2](#) and in [Table 1](#) and summarised below.

Multigene families

A striking feature of the ASFV genome is the large number of genes that belong to one of several multigene families, named MGF 100, MGF 110, MGF 300, MGF 360, MGF 505/530 based on the average number of amino acids encoded by family members. The numbers of copies of these genes varies between virus isolates. This varies between 5 and 13 for MGF 110, 3–4 for MGF 300, 11–16 for MGF 360 and 8–10 for MGF 530/505. The MGF 100 contains up to 5 members. In addition the gene for the p22/KP177R virion transmembrane protein has one or two related copies at the opposite genome end in most of the field isolates although these are missing from the genome of the tissue-culture adapted isolate BA71V. These gene families have evolved on the ASFV genome by a process of gene duplication and transposition from one genome end to the other. The functions are largely unknown although some members of MGF 360 and MGF 505/530 play a role in suppressing the type I interferon (IFN) response. MGF110 encode proteins with signal peptides and conserved cysteine motifs and some members contain the amino acid sequence KDEL which are involved in retrieval of proteins from the endoplasmic reticulum (ER).

Polymerases

ASFV transcription does not require the functional host RNA polymerase II since it proceeds in the presence of inhibitors of the host enzyme. From sequence comparisons with eukaryotic RNA polymerase II, ASFV encoded subunits of a multisubunit DNA-dependent RNA polymerase (RNAP) have been identified. These include subunits 1, 2, 3, 5, 6, 7, 10. This is fewer than the 12 subunits coded for by the eukaryotic RNAP suggesting some mechanistic differences. The RNAP 3 subunit has a C-terminal extension dissimilar to the eukaryotic homologue which may represent a fusion with RNAP subunit 11. In addition ASFV codes for homologues of the eukaryotic transcription factors TFIIB and TFS and a putative TATA Box Binding protein (TBP). In eukaryotes TBP binds to specific promoter sequences, initiator factor TFIIB binds TBP and recruits the RNAP. The elongation factor TFS helps the polymerase move past arrest sites. ASFV codes for proteins with sequence similarity to vaccinia virus encoded transcription factors including the early factor VETFL and late factors VLTF2 and VLTF3.

Transcript modification enzymes have also been identified including a poly A polymerase and 5' capping enzyme with guanylyl-transferase capability. Functional characterisation of the ASFV transcription machinery has however not yet been completed.

DNA replication

Sequence comparisons have identified a processive DNA polymerase family B, involved in genome replication and a putative DNA primase involved in initiating DNA replication. Other proteins involved in DNA replication include a DNA topoisomerase class II involved in unwinding of the duplex DNA during replication and a PCNA like protein, potentially involved in clamping the DNA polymerase to the genome. Other proteins potentially involved in replication include those with motifs of helicases and nucleoside triphosphatases (NTPases) and proteins with similarity to ERCC4-like nucleases and a lambda like exonuclease which may be involved in resolution of head to head concatameric replicating genomes into single units. The proteins involved in DNA replication are not packaged in the virus particle but are expressed early during infection.

Helicases

Six helicases are encoded and presumed to have roles in unwinding/winding DNA or RNA to allow access to the virus transcription or replication apparatus. Of these helicases, three are packaged in the virus particle and likely to have roles in enabling early gene transcription.

Nucleotide metabolism

ASFV encodes genes for several enzymes involved in nucleotide metabolism in order to modulate the pool of dNTPs available for DNA replication. These include ribonucleotide reductase, thymidine kinase, thymidylate kinase, deoxyuridine triphosphatase (dUTPase). There is essentially no synthesis of thymidylate in macrophages and both the thymidine kinase and dUTPase genes are required for replication in porcine macrophages, but not the Vero cell culture line that supports replication of some isolates of

Table 1 ASFV genes and their functions. List of ASFV genes and their functions, as well as uncharacterised proteins that have been identified in purified virions by mass spectrometry. Genes are ordered by function and genes which do not code for virion components and no specific function has been described (such as the multigene family proteins) are not included

<i>Gene Name</i>	<i>Function</i>	<i>Virion Component</i>
Nucleotide metabolism

I215L	Ubiquitin-conjugating enzyme ^a	N

^aIndicates a protein for which there is experimental evidence for its function.

ASFV. It is likely that early expression of these genes increase the dTTP/dUTP ratio to facilitate efficient replication in the macrophage natural target cells for ASFV. These enzymes are not packaged into virus particles.

DNA repair

ASFV codes for components of a base excision DNA repair (BER) system which could be an adaptation required for replication in the highly oxidising environment of the macrophage cytoplasm. The high concentrations of reactive oxygen species (ROS) in macrophages can result in DNA lesions which could either introduce mutations into the viral genome or interrupt reading of the genome by the viral DNA and RNA polymerases. Sequence analysis has identified a DNA polymerase X, an ATP-dependent DNA ligase and a class II apurinic/apyrimidinic endonuclease that could constitute a BER system. A DNA glycosylase is required to initiate the repair process and the apparent lack of an ASFV gene for this enzyme suggests either that the enzyme is a very distant homologue or that the virus recruits a host DNA glycosylase. However, the known components of the BER system are packaged into the virion which implies that the as yet unidentified DNA glycosylase enzyme is also likely to be virally encoded. The BER

pathway is required for replication in the macrophage as deletion mutants lacking the gene for the class II endonuclease are viable in Vero cells, but not macrophages.

Virion morphogenesis and structural proteins

The genes identified as coding for virus structural proteins and those involved in other aspects of virus assembly are shown on [Table 1](#) and on [Fig. 1](#). Initial studies identified virus structural proteins biochemically and mapped the genes for some of these to the virus genome. More recently a proteomic approach using mass spectrometry was used to more fully characterise the proteins present in purified virus particles. The results from these studies generally agree well and are complemented by immunogold electron microscopy to localise proteins in the virus particle. The recent proteomic analysis identified 68 virus proteins in the purified extracellular virions. From these 44 had not previously been characterised and many of these are of unknown function. The major structural proteins include the VP72 (B646L) major capsid protein, the products of polyproteins pp220 and pp62 which are cleaved by a virus encoded SUMO-like cysteine protease into products of molecular weights 150, 37, 34, 14 and 5 kDa or 35, 15 and 8 kDa respectively. These protein products are incorporated into the shell of the nucleoprotein core. Fifteen of the 26 virion proteins containing transmembrane domains were identified in the virus particle and all except one presumed to be incorporated into the inner envelope of the virus particle since only the virus encoded CD2v/EP402R protein has conclusively been shown to be in the outer envelope. Proteins in the inner envelope include several with similarity to the vaccinia virus entry fusion complex and others that have been implicated in virus binding and entry to cells. The vaccinia virus entry fusion complex has 11 proteins each containing a transmembrane domain at either the N or C-terminus but no predicted glycosylation sites or signal peptides. These are features shared with a number of the ASFV virion proteins ([Table 1](#)). Enzymes and factors packaged in the virus also include the RNA polymerase and other components of the early transcription machinery, components of the virus-encoded DNA repair system, others such as two DNA binding proteins, a serine protein kinase and inhibitor of apoptosis protein (see [Table 1](#)).

Proteins that inhibit host defences

By comparison with vaccinia virus, which shares a similar replication cycle to ASFV, it is estimated that more than one third of ASFV encoded proteins may be non-essential for replication in cells but have roles including evasion of host defences or modulation of host cell function.

Inhibitors of apoptosis

ASFV encodes several inhibitors of apoptosis targeting different pathways. These include a member of the Bcl-2 protein family, A179L that binds to a broad range of pro-apoptotic Bcl-2 family members to inhibit their activity. This protein also binds to Beclin-1 and may also inhibit autophagy. The A224L protein belongs to the IAP inhibitor of apoptosis family and has been shown to bind directly to caspase 3 inhibiting its activity. The DP71L protein shares a conserved domain with host protein GADD34 and the Herpes simplex virus-encoded ICP34.5 protein. These proteins up regulate global protein synthesis by targeting host protein phosphatase 1 to dephosphorylate translation initiation factor eIF-2alpha. This activity also prevents translation of a class of mRNAs with short upstream open reading frames that are normally only translated under conditions of cellular stress. These include mRNAs for transcription factors ATF4 and CHOP which activate transcription of genes involved in apoptosis induction. Thus expression of the DP71L protein can this inhibit stress-induced induction of apoptosis. Additional ASFV proteins that inhibit this pathway are predicted since in cells infected with deletion mutants of the DP71L gene stress-induced phosphorylation of eIF-2 alpha is also inhibited.

Inhibitors of type I interferon and inflammatory responses

ASFV encodes a number of inhibitors of the type I interferon response, the main early host response to inhibit virus replication. These were identified either by ectopic expression of ASFV genes identified by sequence comparison or by random screening of ASFV expressed proteins. Alternatively, comparison of type I IFN induction in cells infected with virulent compared to gene deleted attenuated viruses showed that deletion of some genes belonging to MGFs 360 or 505/530 deletion resulted in increased type I IFN induction indicating they function to suppress IFN induction. Other IFN inhibitory proteins include the I329L protein which inhibits the Toll-like receptor 3 activated induction of type I IFN. Other proteins including DP96R inhibit the type I IFN response. Deletion of DP96R, DP148R and MGF 360 and 505/530 genes results in virus attenuation. The A238L protein inhibits transcriptional activation induced by several factors including NF-kB and NFAT mediated by the p300 transcriptional co-activator and its deletion from the virus genome increases several pro-inflammatory responses including TNF-alpha expression, inducible nitric oxide synthesis. The L83L protein has been shown to bind to IL-1 but deletion of the gene did not reduce the virulence of the highly virulent Georgia 2007/1 strain.

Other enzymes

The virus encoded protein kinase, ubiquitin conjugating enzyme and geranyl pyrophosphate synthase may modulate host protein function although their roles are unknown. The protein kinase is packaged in virus particles suggesting it has a role early during infection.

Life Cycle

A diagram of the replication cycle is shown in **Fig. 3**.

Entry

ASFV enters swine macrophages by clathrin-mediated endocytosis as well as macropinocytosis. ASFV can also enter tick midgut phagocytic digestive cells attached to red blood cells. The receptor or receptors on the surface of swine macrophages that ASFV binds to are presently unknown, however it is unlikely to be CD163 as gene-edited pigs lacking this gene are fully susceptible to

Fig. 3 Replication cycle of African swine fever virus. (1) African swine fever virions enter by receptor mediated endocytosis and enter the endosomal pathway. Virions lose their external envelope and the capsid disassembles in a pH dependent manner in multivesicular bodies. (2) The internal envelope fuses with the endosomal membrane and the core enters the cytoplasm. (3) Expression of early genes begins and (4) DNA replication initiates, possibly involving a nuclear step. (5) Virus factories begin to coalesce in a perinuclear regions of the cytoplasm and exclude host proteins except those required for replication, such as the translational apparatus. Viral proteins and DNA accumulate in factories and striking hexagonal assembly intermediates are seen forming on viral membranes. (6) Fully formed intracellular virions egress along microtubules from the factory to the plasma membrane, from which they bud (7) into the extracellular space gaining an external envelope. Some virions are seen on the tips of cellular projections which label for actin.

ASFV. After entry, the outer envelope and capsid is lost in a pH dependent process within endosomal compartments before the inner envelope fuses with late endosomal membranes delivering the core to cytoplasm. Both the intracellular mature form and extracellular enveloped forms of ASFV are infectious. The precise role of individual viral proteins in entry is unclear. P12/pO63R has long been considered an attachment protein, however this protein has now been shown to localise to the inner envelope rather than the outer and therefore may play a role at a later stage of the entry process. Likewise, antibodies that recognise p54/pE184L, p30/pCP204L and p72/pB646L are capable of neutralising infectivity, but these are components of the inner envelope or capsid. Infection of cells with an ASFV conditional lethal mutant with the E248R gene under control of an inducible promoter showed that expression of the pE248R protein is required for fusion of the virion inner envelope with endosomal membranes. This suggests that this protein may be part of an entry fusion complex similar to that identified in vaccinia virus. Bioinformatics analysis showed similarity of some components of the vaccinia virus entry fusion complex with ASFV virion proteins (see [Table 1](#)). The CD2v/pEP402R protein is the only virus protein that has been localised to the outer envelope of virions although it is not essential for virus replication. This suggests that interaction of the virus outer envelope with cells may involve a non-specific interaction although alternative explanations are possible.

Transcription

ASFV gene expression is tightly regulated with immediate early, early, intermediate and late classes of transcripts described. Early gene transcription begins immediately following entry of virus cores into the cytoplasm. RNA polymerase and other factors packaged in the virus core carry out early gene transcription in partial uncoated cores immediately following entry into the cytoplasm. Shut off of immediate early transcripts is dependent on protein synthesis, whereas initiation of intermediate and late gene expression, as well as the shut off of some early transcripts is dependent on viral DNA synthesis. Whole genome transcription data is currently lacking and therefore the temporal expression patterns are restricted to a few known genes. Late genes are predominately structural proteins involved in the assembly and morphogenesis of progeny virions, whereas early genes tend to be involved in modulating the host immune response and replication, although this is not an absolute rule.

DNA replication

DNA replication takes place predominantly in perinuclear cytoplasmic factory areas at a later stage of replication. The similarity between the genome termini of ASFV and poxviruses suggests they share similarities in DNA replication. This is proposed to involve introduction of single strand nicks in the duplex DNA close to genome termini, providing a template for DNA polymerase to synthesise a strand complementary to some of the terminal inverted repeats and terminal loop structure. Subsequently, these strands fold back such that replication can continue along the genome creating duplexes as predominantly head to head concatemers. Resolution of concatameric full length genomes is proposed to involve extrusion or Holliday- like junctions and resolution by virus encoded enzymes. In support of this model head to head genomic fragments have been detected in ASFV infected cells as well as concatameric genomes of double unit length. An early phase of DNA replication takes place in the nucleus of infected cells and ASFV DNA has been observed juxtaposed to the inner nuclear envelope. Low molecular weight fragments of DNA are synthesised in the nucleus and cytoplasm early during the replication cycle with larger intermediate and full length fragments appearing exclusively in the cytoplasm. It is tempting to speculate that the sub-genomic fragments synthesised in the nucleus are transported to the cytoplasm where they act to prime full length genome synthesis. However evidence for this model is currently lacking since radioactive label incorporated into the shorter fragments could not be chased into the full length genome.

Assembly and morphogenesis

Progeny virions are assembled in discrete perinuclear regions of the cytoplasm called virus factories. Formation of these replication sites coincides with the initiation of cytoplasmic DNA synthesis, however the morphology of virus factories change as replication progresses and serve to concentrate and organise translation, transcription, DNA synthesis and assembly within one cellular compartment. Virions are assembled on the inner envelope with the capsid assembled on the convex surface and the core on the concave. Intermediate forms resembling half formed hexagons are readily visible within virus factories. The inner envelope consists of a single lipid bilayer which by comparison to vaccinia is likely stabilised in part by the major capsid protein, p72. The endoplasmic reticulum has been suggested as the source of the membrane used for the inner envelope, however this was in part based on the detection of viral and cellular endoplasmic reticulum proteins in purified virions by immunoblot which were not present when virions were analysed by mass spectrometry. Membrane targeting of virus proteins is crucial for ASFV morphogenesis. Assembly of the p72 on the convex surface is dependent on a virally encoded chaperone pB602L and correct processing of pp220 into its mature proteins is dependent on myristoylation, as well as the viral protease pS273R mentioned above. Formation of the nucleocapsid and DNA packaging is poorly understood, however is dependent on the prior formation of the core as deletion mutants lacking pp220 and pp62 form 'empty' particles that lack the electron dense nucleocapsid. Once complete, pE120R mediates the transport of virions along microtubules by kinesin motor proteins to the plasma membrane where they gain their external envelope as they bud out of the cell. ASFV can also induce filopodia like actin projections at the cell surface which may aid cell-to-cell spread.

Epidemiology

African swine fever virus (ASFV) was first identified in Kenya in the early 20th century as the cause of a highly lethal disease of domestic pigs that was initially called East African swine fever and later African swine fever (ASF). Wild African suids, in particular the warthog were considered the most likely source of infection. Warthogs did not show clinical signs but spread disease to domestic pigs which they came into contact with. Subsequently, other African wild suids, including the bushpig, red river hog and giant forest hog were also shown to be infected without clinical signs. Soft ticks of the *Ornithodoros* species which inhabit warthog burrows were later shown to be biological vectors of ASFV. The virus can persistently infect ticks over long periods and be transmitted between them transstadially and transexually. Transovarial transmission has been demonstrated for *O. moubata*, the tick vector present in warthog burrows. The virus is very well adapted to replication in hosts in the ancient sylvatic cycle and presumed to have been present over a very long time period. This is supported by the higher genetic diversity of isolates from the regions where this cycle is present.

ASF was subsequently identified in some other East African countries where the ancient sylvatic cycle is present. Since then the virus spread through central and West Africa and is now endemic or causes sporadic outbreaks in almost all sub-Saharan Africa. However, the ancient sylvatic cycle has not been described apart from in East Africa. The virus was contained in sub-Saharan Africa until the late 1950s when there were outbreaks in Spain and Portugal, this was followed with further outbreaks across Western Europe, the Caribbean and Brazil until the 1990s when disease was finally eradicated, although ASFV remains endemic in Sardinia. In 2007 ASFV spread into the Caucasus and from there to the Russian Federation. From 2013 further spread to Eastern Europe was observed. More recently there has been an increase in outbreaks across Europe including: Moldova in September 2016, Czech Republic in June 2017, then Romania in July 2017, followed by Hungary in April 2018, and Bulgaria in August 2018. ASFV was also identified in wild boar in Belgium in September 2018. In addition to European outbreaks ASFV has also been identified for the first time in China in August 2018, with the initial report in the Liaoning region in North East China and has since been reported throughout the country, including Beijing. The virus also appeared in Mongolia in January 2019. The current spread of ASFV presents an enormous threat to the global pig industry.

ASFV can be transmitted through multiple routes including direct contact with infected animals, tick bites, fomites, and contaminated pig products. ASFV is transmitted by direct contact with the virus and in sub-Saharan Africa it is also transmitted by the soft tick *Ornithodoros spp.*, acting as a viral vector. ASFV can be transmitted through direct contact with infected blood which contains up to 10^9 infectious units of virus per ml, or saliva, urine or faeces each of which can contain up to 10^5 infectious units per ml/mg. ASFV has also been shown to be spread by fomites such as feed, equipment and vehicles. Contaminated pig products are another source of infection, with ASFV persisting for months in pork products. This also highlights the risks associated with swill feeding in transmission of ASFV. There is also potential of secretions from infected wild boar being a risk to transmission, by contaminating the environment that is potentially shared with domestic pigs. Wild boar pose another route of transmission to domestic pigs, as in Europe wild boar are equally susceptible to ASFV, and there has been observations in recent outbreaks of dead wild boar from ASFV in the vicinity of ASF-affected farms, as well close to national borders, with some reports suggesting that pig and wild boar interactions with carcass sites play a role in ASFV transmission.

Clinical Features

The clinical signs caused by ASFV infection vary depending on the virus isolate and host. The virus is very well adapted to its ancient wildlife hosts in eastern and southern Africa. These include several wild suid species such as warthogs, bushpigs and red river hogs and soft ticks of the *Ornithodoros* species. In these hosts few clinical signs are observed but virus can persist in tissues, particularly spleen and lymph nodes. In warthogs and bushpigs experimental infection with highly virulent ASFV was observed to cause a transient low fever coincident with a peak of replication in blood. In contrast ASFV infection in domestic pigs and wild boar generally results in an acute haemorrhagic fever with a very high case fatality approaching 100%. Different courses of ASF disease have been described in the field and in experimental infections. Highly virulent isolates can cause a peracute disease which may result in death within 4 days post-infection (dpi) without evident lesions and an acute form of disease which can result in death of almost all infected pigs within 4–21 dpi. In subacute disease forms, caused by moderately virulent isolates, incubation periods are longer, clinical signs tend to be less marked and mortality rates are lower varying between 30% and 70%. A typical disease course results in early clinical signs of fever, reduced eating or loss of appetite and increasing inactivity and lethargy or morbidity. External signs of haemorrhage including cyanosis or skin reddening around the tips of ears, and other extremities, conjunctivitis, bloody diarrhoea can be observed but animals may die without these signs. Clinical signs may typically be observed starting from 3 to 5 dpi but this may vary depending on the dose, route of infection or virus isolate involved. Lower virulence isolates can cause chronic forms of disease characterised by low mortality but signs such as delayed growth, emaciation, joint swelling, skin ulcers and lesions. Some pigs may remain persistently infected with virus in lymph tissues over a prolonged period. Infections of wild boar are clinically very similar to that in domestic pigs and result in similar fatality rates.

Pathogenesis

The main target cells for ASFV replication are those of the myeloid lineage. Monocytes and macrophages at an intermediate to late stage of differentiation are most susceptible to productive infection. Cell markers determining susceptibility to infection have not

been clearly defined. There are reports indicating that dendritic cells may also be susceptible to infection. Vascular endothelial cells have been shown to be infected in cell culture. At later stages of acute disease in animals several other cell types, including lymphocytes and platelets, have been observed to contain virus particles or proteins although virus replication does not occur.

The oral-nasal route is the main route for ASFV infection in suids. In areas where the *Ornithodoros spp* soft tick plays a role infection by tick bites may occur. Following infection the virus replicates mainly in mononuclear phagocytic cells in the tonsils, sub-mandibular or other lymph nodes and spreads through lymph and blood to secondary organs of replication. The virus encodes a number of proteins that inhibit apoptosis but at later stages of the replication cycle apoptosis of the infected cells is observed. Spread of virus in apoptotic bodies may provide a mechanism for virus spread avoiding inflammatory responses induced by necrotic cell death. Virus replication in macrophages has been reported to result in activation of both infected and bystander uninfected macrophages as detected by immunohistochemistry and measured by increased phagocytosis and cytokine secretion. A feature of acute ASF disease is the massive apoptosis observed in both T and B lymphocytes in infected tissues and blood. This apoptosis is observed in uninfected bystander lymphocytes in infected tissues, particularly surrounding infected macrophages. This suggests that factors on the surface of or secreted from infected macrophages are involved in inducing the apoptosis of lymphocytes. Little is known of the mechanism by which apoptosis is induced although TNF-alpha has been identified as a possible contributing factor. In acute and sub-acute forms of disease, ASFV replicates rapidly at primary and secondary sites in lymph tissues including spleen and spreads systemically in blood. This indicates a failure of the host's early innate responses to control virus replication, presumed mainly to result from the many and diverse mechanisms the virus has to inhibit these responses. High levels of virus replication in blood result in typical signs of haemorrhagic pathology including destruction of vascular endothelial cells, leakiness of blood vessels, thrombo and lymphocytopenia and induction of disseminated intravascular coagulation. Typically very high levels of virus replication are observed in blood, up to 10^8 or 10^9 per ml. In some infected animals with moderately virulent isolates, levels of virus replication in blood are lower (up to 10^6 to 10^7 per ml) and some individuals may recover from clinical signs. In pigs infected with low virulence isolates transient low levels of virus in blood may be observed and low levels of virus replication in tissues are detected. Animals that recover may be persistently infected over a period of at least several months. In experimental studies virus was shown to be cleared from persistently infected animals.

Immune Responses

African swine fever virus typically causes a lethal haemorrhagic fever in affected swine, however survivors discovered in the field were found to have robust immunity against homologous strains of the virus. Isolates of reduced virulence obtained from both the field and through experimental passage through tissue culture permitted a more thorough analysis of the immune response to African swine fever and mechanisms that contribute to protection.

Pigs infected with virulent strains of the virus typically exhibit titres of 10^7 – 10^9 infectious units of virus per millilitre of blood. This in combination with high serum levels of pro-inflammatory cytokines such as interferon, tumour necrosis factor alpha and interleukins -1 β , -6 and -8 likely contribute to the lymphopenia and other pathological signs seen in animals suffering acute forms of the disease. A combination of rapid viral replication, disease progression and immunosuppression are likely responsible for the failure to generate ASFV-specific adaptive responses in naïve animals infected with virulent strains of the virus.

Animals infected with low virulence strains typically do not display elevated serum levels of cytokines, but develop both humoral and cellular immune responses that protect animals from acute disease induced by related virulent strains of the virus. Antibodies of the IgM class specific to ASFV first appear between 7 and 11 days post infection and those of the IgG class appear from 14 days onwards. Serum from recovered animals can neutralize ASFV infectivity in vitro as well as mediate lysis of infected cells. The importance of the antibody response in protecting animals from acute disease caused by virulent ASFV strains has been demonstrated by experiments where serum was passively transferred to naïve pigs. Proliferation of ASF specific lymphocytes can be seen from 10 days post infection with attenuated strains of the virus. Pigs recovered from attenuated ASF infection have circulating T-cells that secrete interleukin-2 and interferon gamma after re-exposure to virus, as well as T-cells that have ASFV-specific cytolytic activity. Antibody depletion studies with anti-CD8 monoclonals have shown that the cellular response is essential for the protection afforded by low virulence strains of ASFV. Current research is focussed on identifying precise correlates of protection and identifying which of the 150 or more open reading frames encode for protective antigens.

Diagnosis and Control

Diagnosis of ASF requires laboratory confirmation since clinical signs are similar to several other diseases including classical swine fever (CSF). Detection of virus genome by polymerase chain reaction (PCR) is the usual method used for diagnosis. Detection of infectious virus by replication in primary porcine macrophage cultures is also used, in order to confirm the presence of, and characterise, infectious virus. The haemadsorption of red blood cells to infected monocytes/macrophages or immunofluorescence using antibodies against one of the virion proteins is used to detect infection in cell culture. Kits are commercially available to detect virus antigen by ELISA or using lateral flow devices but the sensitivity of these tests is lower than PCR or virus isolation and they should not be used as the only detection method.

Detection of ASFV specific antibodies using ELISA assay can be used in some situations to identify animals that have been infected. Pigs or wild boar infected with highly virulent isolates usually die before an antibody response is detected. Therefore this method alone is not recommended as the only diagnostic test to detect infection. Detection of ASFV specific antibodies can indicate that isolates of reduced virulence are circulating. To obtain a more complete assessment of the epidemiological situation both ASFV antigen and specific antibodies is recommended.

African swine fever is a notifiable disease to the OIE (World Organisation for Animal Health) as well as national and other international veterinary services. Following confirmation of an ASF outbreak in pigs, veterinary authorities in most countries will cull animals on infected premises and disinfect the premises. In addition movement of pigs is banned from a surrounding protected zone and surveillance for ASF carried out in a wider zone. Infection results in a ban of export trade from the infected area. Varying strategies are applied in different countries to allow continued trade internal to the country or region (for example the EU). If infected wild boar are detected control is more difficult to implement. Following a single point of introduction of ASF to wild boar in the Czech Republic in 2017, disease was eventually eradicated by fencing an extended infected zone and shooting all wild boar in this zone. Reducing contact between wild suids and domestic pigs can also help control ASFV spread particularly if combined with improved on farm biosecurity. In S. Africa double fencing of farms in areas where ASFV infected wildlife are present has proven effective in preventing outbreaks on farms.

The availability of a vaccine would increase options for control. It was established in the 1950s and 1960s that pigs that recover from infection with less virulent strains of ASFV are protected against challenge with related virulent viruses, indicating that vaccine development should be successful. However inactivated virus does not induce protection against challenge even when delivered with recent adjuvants. Moreover it has proven difficult to develop a subunit vaccine since the complexity of the genome makes it difficult to identify protective antigens. Live attenuated vaccines are the most promising approach for vaccine development in the shorter term since high levels of protection can be achieved in the absence of significant replication of the challenge virus. Live attenuated strains isolated from the field have provided excellent models for understanding mechanism of protective immunity but safety issues have precluded their commercial development. Rational attenuation of virus by gene deletion has provided a number of very promising candidates for further evaluation. Deletion of genes that control innate immune responses, in particular the type I interferon response, has been an effective mechanism to attenuate virulent ASFV and induce a protective response. Delivery of live attenuated vaccines in baits to wild boar was successfully used in the eradication of CSFV from Europe and should also be effective for ASFV.

Akabane Virus and Schmallenberg Virus (*Peribunyaviridae*)

Martin Beer and Kerstin Wernike, Friedrich-Loeffler-Institute, Insel Riems, Germany

© 2021 Published by Elsevier Ltd.

Glossary

Ankyloses Abnormal stiffening and immobility of a joint due to fusion of the bones.

Arthrogryposis Rigid fixation of the joints.

Brachygnathia Shortness or recession of the mandible.

Dystocia Abnormal labor or parturition.

Encephalomyelitis Inflammation of the brain and the spinal cord.

Hydranencephaly Replacement of the brain's cerebral hemispheres by sacs filled with cerebrospinal fluid.

Kyphosis Abnormally excessive convex curvature of the spine.

Lordosis Excessive inward curvature of the spine.

Micromyelia Abnormal smallness or shortness of the spinal cord.

Nystagmus Involuntary, rhythmic oscillating motions of the eyes.

Porencephaly Small cavities in the brain substance.

Scoliosis Lateral deviation of the spine.

Strabismus Condition in which the eyes do not point in the same direction.

Torticollis Twisting of the neck causing the head to rotate or tilt.

Introduction

The genus *Orthobunyavirus* consists of more than 170 viruses and comprise several members of public health or veterinary importance. Among the viruses that cause diseases in animals are Akabane virus and Schmallenberg virus, which infect predominantly ruminants and are able to cross the placental barrier and induce fetal malformation. Both Akabane virus and Schmallenberg virus, are transmitted between their mammalian hosts by blood-sucking insect vectors, specifically biting midges of the genus *Culicoides*.

While Akabane virus was initially described in the 1950th, Schmallenberg virus has been discovered for the first time in 2011. Both viruses are named according to the place of origin of the samples, in which the viruses were detected for the first time. Akabane virus was initially detected in mosquitoes caught in a village in Japan, and Schmallenberg virus was isolated from the blood of acutely infected cattle kept near the German city of Schmallenberg.

Classification

Akabane virus and Schmallenberg virus are members of the genus *Orthobunyavirus* in the family *Peribunyaviridae* (order *Bunyavirales*). Orthobunyaviruses are grouped into 18 serogroups on the basis of serological relatedness and both, Akabane virus and Schmallenberg virus, belong to the Simbu serogroup. Further Simbu serogroup viruses are for example the eponymous Simbu virus, Aino virus, Douglas virus, Peaton virus, Sathuperi virus, Shamonda virus, and Shuni virus. All of them infect animals. The only known zoonotic member of this serogroup is Oropouche virus, which is present in South America.

Virion Structure

Akabane and Schmallenberg virions are spherical, about 100 nm in diameter and relatively simple in their composition, possessing only four structural proteins: the nucleocapsid protein, the viral RNA-dependent RNA polymerase and the surface glycoproteins Gn and Gc. The nucleocapsid protein encapsidates the three RNA segments to form ribonucleoprotein complexes, which associate with the viral RNA-dependent RNA polymerase and are contained within the envelope of the particle (Fig. 1). The viral envelope consists of a lipid layer, which is derived from the Golgi complex of the host cell. On the surface of the virions, locally ordered lattice of spikes protrude from the membrane. These spikes consist of the glycoproteins Gn and Gc, which form heterodimers via disulfide bonds and are anchored in the lipid envelope (Fig. 1).

Genome

The genome of Akabane virus and Schmallenberg virus consists of three segments of negative-stranded RNA, which are named according to their size as large (L), medium (M), and small (S) segment. The L-segment encodes the viral RNA-dependent RNA polymerase. The M-segment encodes the surface glycoproteins Gn and Gc, as well as a non-structural protein (NSm) in the coding

Fig. 1 Virion morphology and genome organization of Schmallenberg virus. The genome consists of three segments of negative-stranded RNA, which are referred to as S, M, and L. The genomic segments have complementary terminal sequences that may base-pair and form circular or panhandle structures. The three RNA segments are encapsidated by the nucleocapsid protein (N) to form ribonucleoprotein complexes, which associate with the viral RNA-dependent RNA polymerase and are contained within the lipid envelope of the particle. The glycoproteins Gn and Gc are inserted in the membrane. Reprinted from Wernike, K., *et al.*, 2014. Schmallenberg virus-two years of experiences. *Preventive Veterinary Medicine* 116 (4), 423-434, Copyright (2014), with permission from Elsevier.

order Gn-NSm-Gc. The S-segment encodes the nucleocapsid protein and the non-structural protein NSs in alternative overlapping reading frames. The three RNA segments have complementary terminal sequences and, as a consequence, the RNAs may base-pair and form circular or panhandle structures (Fig. 1).

Viral Replication

The basic features of the replication cycle are similar to those of other Bunyaviruses, although insect-transmitted viruses such as Akabane virus and Schmallenberg virus have to multiply in two different hosts, i.e., the insect vectors and the mammalian hosts.

Cell entry, which occurs by clathrin-mediated endocytosis, involves interactions between the viral glycoproteins Gn and/or Gc and cell surface receptors, which have not been yet identified. Uncoating of the viral particles likely occurs when the endosomes become acidified, thereby initiating fusion of the viral membrane and endosomal membrane. After the release of the ribonucleoprotein complexes into the cytoplasm, the genomic RNA is transcribed into messenger RNAs (mRNAs) by the virion-associated RNA polymerase. This process is termed primary transcription. The viral RNA polymerase exhibits, in addition to its polymerase activity, an endonuclease activity and this is used to recruit primers for RNA transcription from the host cell mRNA (so-called cap-snatching mechanism). During translation of the mRNA, the virion-associated RNA polymerase switches from primary transcription to replication. Following translation of the primary transcripts into viral proteins, the genome is replicated via a complementary full-length positive-strand RNA, the so-called antigenome, and then further mRNA synthesis ensues, which is termed secondary transcription.

Maturation occurs at the membranes of the Golgi complex. The ribonucleoproteins are transported to the Golgi apparatus that has been modified by the insertion of the viral glycoproteins Gn and Gc. After budding into Golgi membrane-derived vesicles, the viral particles are trafficked to the cell surface via the exocytic pathway involving actin filaments. Subsequently, the fusion of the vesicular membranes with the plasma membrane leads to the release of infectious virions.

Epidemiology

Akabane virus, Schmallenberg virus and other orthobunyaviruses persist in nature by alternate cycling of the virus between mammalian hosts and midges after biting of the mammalian host by the insects. The geographical distribution of the viruses depends on the distribution, seasonal activity, and abundance of the insect vectors responsible for their transmission.

Most of Africa, the Middle East, Asia, and Australia may be regarded as being endemic for Akabane virus. Schmallenberg virus initially emerged in the German/Dutch border region and, thereafter, spread throughout the European continent reaching the Scandinavian countries and the British Isles at the North, the Mediterranean region at the South and Eastern European countries such as Poland, Lithuania and Russia. Within endemically infected areas, Akabane virus and Schmallenberg virus established patterns of cyclic circulation, meaning that for one or perhaps two seasons the viruses are detected only sporadically, while in the intermediate years the viruses re-appear to a greater extent. The differences in the level of virus circulation are presumably related to the overall herd immunity rate in the ruminant population and to the abundance of the vector insects, which is influenced by climate.

The principal vectors of Akabane virus, Schmallenberg virus and further Simbu serogroup members are small biting midges of the genus *Culicoides*. Multiple *Culicoides* species are often present in the same place at the same time. From an epidemiological perspective, important considerations are the infection rates of *Culicoides* with Akabane or Schmallenberg virus and the vector competence, i.e., the physiological ability of a vector organism to acquire, maintain and transmit an infectious agent. The Simbu serogroup viruses are transmitted from the insect vectors to the mammalian hosts with a high level of efficiency, partly because of the relatively high virus infection rates of the *Culicoides* midges and the large number of individual *Culicoides* that may attack an animal. Akabane virus has been detected in the *Culicoides* species *C. brevitarsis*, *C. oxystoma*, *C. imicola*, *C. milnei* and *C. wadai*, while the following *Culicoides* species were implicated in the transmission of Schmallenberg virus: *C. obsoletus* sensu stricto, *C. scoticus*, *C. chiopterus*, *C. dewulfi*, and *C. nubeculosus*. Experimental infection studies with laboratory reared lines of *Culicoides* provided evidence of successful dissemination in *C. sonorensis*. Although Akabane virus has been initially isolated from mosquitoes, they are not considered to be true competent vectors of neither this virus nor of Schmallenberg virus.

In regions with a temperate climate, there is a distinct seasonal pattern of virus transmission, which coincides with warm, moist summer and autumn months and is a consequence of the abundance of the insect vectors. Insect numbers start to increase in the late spring and early summer months, usually peak in early autumn and virus transmission ceases with the onset of very low temperatures and the first frosts. Even in subtropical and tropical regions, there is a tendency towards seasonal transmission, with the highest infection rates in summer and declining transmission rates in the periods of lower rainfall.

Clinical Features

Akabane virus and Schmallenberg virus infect predominantly ruminants. Clinical symptoms have been observed only in domestic animals so far. Direct and indirect detections in association with clinical signs have occurred in adult cattle, sheep, and goats or in their fetuses or newborn offspring.

In addition, Schmallenberg virus genome has been detected in several wild and exotic ruminant species such as alpacas, llama, mouflon, water buffalo or elk.

Furthermore, antibodies against Akabane virus have been found in horses, pigs, camel, deer, and a wide selection of African wildlife, while no infections have been detected in marsupials in Australia. Antibodies against Schmallenberg virus have been detected in various domestic and wild ruminants, free-ranging wild boar, and a range of ungulates kept in European zoos, but clinical signs related to Akabane or Schmallenberg virus infections have not been described in any wild or exotic species.

An infection of adult domestic ruminants with Akabane virus or Schmallenberg virus is either asymptomatic or associated with mild, short-lasting, non-specific clinical signs such as fever, decreased milk production, or diarrhea. Some strains of Akabane virus may induce encephalitis in newborn calves in rare cases and the Iriki strain of Akabane virus, which is present in Japan and Korea, has been occasionally associated with cases of encephalitis in adult cattle.

In contrast to the mild symptoms observed in adult animals, both viruses have significant impact on developing fetuses. When naïve dams are infected during a critical phase of gestation, the viruses can cause stillbirth or premature birth, the birth of mummified fetuses or severe congenital malformations known as “arthrogryposis-hydranencephaly syndrome” (AHS). The range of defects and the percentage of affected newborns varies depending on the herd management and the time period of virus transmission. In herds with a year-round mating system, the full range of congenital defects may be seen, while in herds with a very restricted, seasonal mating period, only a few types of abnormality may be noticed.

An infection early in pregnancy may be associated with embryonic or fetal death and/or abortion, given that an increased number of repeated estrus cycles, which suggest early embryonic or fetal loss, and an increasing rate of abortions have been reported from affected flocks. When fetuses are infected in early to mid-gestation, the viruses may induce congenital lesions. The most common lesions affect the skeletal muscle, the central nervous system and/or the axial skeleton; lesions can affect either one system or can occur in combination. Affected animals may show arthrogryposis ([Fig. 2](#)) associated with histological evidence of muscular hypoplasia, characterized by a reduction in number and diameter of the myofibrils, which may be associated with a loss of cross-striation in myofibrils and fatty replacement. In the central nervous system, the most common lesions are hydranencephaly, porencephaly, cerebellar hypoplasia and micromyelia. These lesions are sometimes associated with nonsuppurative encephalomyelitis and neuronal degeneration and necrosis. The animals are either stillborn or, in cases of less severe malformation, born alive. The following clinical signs or behavioral abnormalities suggestive for lesions in the central nervous system have been described in alive newborns: hypertonicity, hyperreflexia, depression, blindness, ventrolateral strabismus, nystagmus, deafness, dullness, inability to stand, inability to suckle, or aimless wandering. The animals may also display vertebral malformations, including lordosis, kyphosis, scoliosis, torticollis, ankyloses or brachygnathia inferior. These lesions can also appear in isolation with no other clinical sign. In sheep and goats infected with Akabane virus, there may also be pulmonary hypoplasia, which has not been observed after Schmallenberg virus infections. The described defects are usually life-threatening and most affected animals die after birth or are euthanized. The nature of the musculoskeletal and nervous lesions is similar in cattle and sheep. However, only a proportion of newborns whose mothers were infected during gestation show clinical signs or pathomorphological alterations. Even the birth of one malformed and one healthy offspring within the same litter has been described. In cows or ewes delivering severely malformed offspring, dystocia is common and, as a consequence, many of those animals require embryotomy or Caesarian section.

Fig. 2 Genesis of fetal malformations in calves and lambs after infection of their mothers with Akabane virus or Schmallenberg virus during a critical period of pregnancy. When naïve dams are infected, they show a short-lived viremia during which the virus may be transmitted to the developing fetus. Dependent on the stage of pregnancy, fetal infections can lead to stillbirth, premature birth, dystocia or varying degrees of malformation. Modified from Höper, D., *et al.*, 2012. Schmallenberg-Virus, ein neues Virus in Europa. Deutsches Tierärzteblatt 4 (2012), 500-505, with permission.

Pathogenesis

The onset of the two to six days lasting viremia usually occurs one to six days after infection and, in most cases, is not accompanied by clinical signs. The viruses are not associated to any blood cell population, but are circulating freely in the serum, which might assist in their timely elimination from the blood stream.

Similarly to other orthobunyaviruses, the NSs protein of Akabane virus and Schmallenberg virus represents an important virulence factor. In infected mammalian cells, the NSs protein counteracts the shutoff of host cell protein synthesis and the induction of interferon. In addition, NSs is involved in other functions like the regulation of translation, apoptosis, and viral polymerase activity. Viruses, in which the NSs protein has been deleted by reverse genetics, do not induce detectable virus replication in interferon-competent hosts.

As mentioned above, when naïve pregnant animals are infected, the viruses may replicate in the placenta and cross the placental barrier resulting in either abortion, premature birth, still birth or varying degrees of fetal malformation depending on the time of gestation when infection occurred. The susceptibility of the growing embryo or fetus to an infection depends on the maturity of the placentomes and fetal target organs and on the development of the fetal immune system. If the infection of naïve pregnant female takes place before the first placentomes are established (between days 30 and 45 after conception in ruminants), the embryo may be protected from viral invasion. The second key point is related to the maturation of the fetal immune system, since the critical timeframe for the induction of malformations is most probably limited to the time before the fetus becomes immunocompetent. Bovine fetuses develop first antibodies between days 60 and 150 of gestation while in lambs, immunocompetence develops from 65 to 70 days of pregnancy. Consequently, the timeframe during which an infection might lead to malformation ranges from about 30 to 150 days after conception in cattle and from about 30 to 60 days in small ruminants (Fig. 2). Target cells of the viruses within the developing fetuses are neurons in the cerebral cortex, brainstem and spinal cord. An infection of these cells during ontogenesis leads to malformation of the central nervous system such as hydranencephaly, porencephaly, cerebellar hypoplasia or micromyelia. The effects on skeletal muscle are mainly secondary, although a primary viral myositis sometimes occurs. Arthrogryptic newborns show restrictions to movements of the limb joints, which is a result of changes of the soft tissues. The joint surfaces are usually normally developed and the bones are unaffected, while the muscles are

usually reduced in size and paler in color than normal, which is a result of both, neurogenic muscular atrophy and primary infection of the muscles.

Most of the births of dead and/or malformed lambs and calves induced by Akabane virus or Schmallenberg virus infections of their mothers were reported after full-term pregnancy, leading to a time gap of several months between infection and birth (Fig. 2). However, not every infection during the critical period of pregnancy leads to the transplacental transmission of the virus to the fetus. Furthermore, the crossing of the placental barrier does not inevitably result in abortion or fetal malformation. The incidence of affected fetuses or newborns varies depending on the virus, and in the case of Akabane virus, on the strain, but it is usually low. For Schmallenberg virus, an average malformation rate of about 0.5%–3% was estimated for cattle, while on average of 8% of lambs born in infected herds showed typical congenital malformation. However, in some sheep holdings, more than 30% of the pregnant ewes of a lambing season aborted or gave birth to malformed offspring. In cattle naturally infected by Akabane virus, the incidence of defects may be, dependent on the virus strain, as high as 25%–50%, if the animals are infected at the most critical stages of gestation with a very virulent strain. In sheep infected at the most susceptible stages of gestation, the incidence of fetal infection can range from 15% to 80%.

When fetuses are infected once they are immunocompetent or become able to develop specific antibodies during an ongoing infection, the antibodies produced by the fetus itself might assist in the clearance of the virus from the fetus. Due to the occasional elimination of the virus between infection of the fetus and birth, some newborns suspected of Akabane virus or Schmallenberg virus infection test negative for virus or viral RNA. However, the presence of antibodies in the blood of the newborns before the intake of the colostrum of their mothers might be used for diagnostic purposes.

In adult animals, first neutralizing antibodies are commonly detectable between two and three weeks after infection and they prevent from reinfection with the same virus type. Akabane virus-specific antibodies are measurable for at least two years and antibodies against Schmallenberg virus usually persist for many years, if not even lifelong.

Maternally-derived antibodies, which are transferred from seropositive dams to their offspring by colostrum ingestion during the first hours of life, decay over time and are not measurable any more after five to six months.

Diagnosis

The most widely used method for the direct virus detection is the analysis of viral RNA by reverse transcription polymerase chain reaction (RT-PCR) or real-time RT-PCR. Different RT-PCR assays targeting either the L-, M-, or S-segment of either Akabane virus or Schmallenberg virus have been developed. Furthermore, group-specific real-time RT-PCR assays, which allow for the detection of all members of the Simbu serogroup, have been established. In addition to the detection of viral RNA, the viruses can be isolated on insect cell lines (e.g., *Culicoides variipennis* larvae (KC) cells) or mammalian cell lines (e.g., baby hamster kidney (BHK) or African green monkey (Vero) cells). Test systems for antibody detection include micro-neutralization, indirect immunofluorescence tests and various in-house or commercially available ELISAs.

The choice of the sample material is critical for both, virus or viral genome and antibody detection. In adult animals, the preferred material for detecting acute infections and for antibodies is serum, with the detection of virus or viral genome being time-restricted by the short viremia of only a few days. Suitable sample materials for virus or viral genome detection in malformed fetuses or newborns include different parts of the brain, placenta, meconium, and hair swabs (= amniotic fluid collected by a swab from the hair of the fetus or newborn). However, not all calves or lambs by clinical presentation suspected of Akabane virus or Schmallenberg virus infection test positive by RT-PCR. The most accepted explanation for this phenomenon is that the virus, which has caused the initial lesions weeks or months before abortion, stillbirth or birth, is no longer present in the newborn. In addition to the direct virus detection, the detection of antibodies in fetuses or newborns is also a valuable tool to confirm a congenital infection, when serum samples are taken prior to colostrum intake or when fetal heart blood is used as sample matrix from aborted or stillborn fetuses.

For differential diagnosis in cases of newborns showing congenital defects, other teratogenic pathogens should be taken into consideration. Examples include further Simbu serogroup viruses such as Shuni virus or Aino virus, other bunyaviruses (e.g., Cache Valley virus, Rift Valley fever virus) or further viral agents including bovine viral diarrhea, border disease, bluetongue, Chuzan or Wesselsbron viruses. Furthermore, a range of non-infectious causes of fetal malformation such as maternal intoxication (e.g., by ingestion of toxic plants) or an inherited defect should also be considered.

Prevention

Treatment options are not available, but there are two main approaches for prophylaxis: management strategies and vaccination. As Akabane virus and Schmallenberg virus are transmitted by insect vectors, insect-proof nets or mesh to shield animal housing or the use of insecticides or repellents could be taken into consideration to prevent potentially infected vectors from biting susceptible animals. However, case-control studies provided either no or only little evidence for protective effects of those treatments.

An option to prevent from transplacental transmission of the virus from the dam to the developing fetus could be an intelligent management system. At least in regions with temperate climate, the mating period could be adjusted in order to avoid that susceptible animals are in the critical phase of gestation during the season of the highest activity of the insect vectors, i.e., in

summer and autumn. When grazing is used, another option is to adapt the management system and keep young animals outside during the major vector season. In this way, young animals are exposed to insect vectors, which might potentially lead to an infection. The immunity acquired in the course of an infection early in life may prevent fetal infection during a later pregnancy. However, this management concept requires a high number of infected insect organisms every year and a very high transmission rate of the virus from the vector to the animal host to ensure that every young animal is bitten and infected. Therefore, a much more reliable method of prophylaxis is vaccination.

Akabane vaccines have been produced in Japan and Australia. In both countries, inactivated vaccines have been developed either as monovalent Akabane vaccine or as multivalent vaccines to prevent infections with Akabane virus, Aino virus and the likewise teratogenic reovirus Chuzan virus. The vaccination scheme involves two immunizations administered four weeks apart from each other and annual revaccination is recommended. In experimental infection trials, the vaccines were safe when used in pregnant animals. In addition to inactivated vaccines, a live attenuated vaccine has been produced in Japan by serial passage of Akabane virus in cell culture. This vaccine likewise prevents from infection. However, in pregnant ewes this vaccine may cause intrauterine infection of the fetus and, therefore, it is not recommended for use in sheep.

Immunization with inactivated Akabane vaccines do not lead to an *in vivo* cross-protection against Schmallenberg virus infections. Against infections with Schmallenberg virus, virus-specific monovalent inactivated vaccines have been licensed for the European market. These vaccines confer a protective immunity in cattle after two immunizations administered three weeks apart, while sheep have to be vaccinated only once. Annual revaccination is recommended. Apart from inactivated vaccines, live-attenuated, subunit, DNA-mediated and live-vectored vaccines have been developed, but none of them is currently commercially available.

Glossary

Arbovirus Virus maintained in an infection cycle involving hematophagous arthropods and vertebrate hosts.

Encephalitis Inflammation of the brain associated with cognitive changes.

History

Nomenclature of the encephalitic alphaviruses recognizes the characteristic geographic distribution of each and the initial identification of the viruses as causes of encephalitis in horses. The first clear record of epidemic equine encephalitis is from 1831, when an outbreak in Massachusetts, USA, resulted in the deaths of 75 horses. Over the next 100 years several outbreaks of encephalitis in horses occurred along the Atlantic seaboard. The virus causing eastern equine encephalitis (EEEV) was first isolated from the brain of an affected horse in 1933 by Tenbroek and Merrill. However, two years earlier Meyer, Haring and Howitt had isolated a virus from the central nervous system (CNS) tissues of two horses involved in an epidemic of equine encephalitis in the San Joaquin Valley of California. EEEV and the Western equine encephalitis virus (WEEV) were antigenically distinct. Both diseases occurred in summertime epidemics, and in 1933, Kelsor showed that mosquitoes could transmit WEEV and shortly thereafter mosquito transmission of EEEV was demonstrated. In 1938 both EEEV and WEEV were isolated from humans with encephalitis occurring in the same regions as the equine cases. In 1936 equine encephalitis occurred in the Goajira region of Venezuela and the virus causing this epizootic, isolated independently by Beck and Wyckoff and Kubes and Rios, was not neutralized by sera from animals immunized with EEEV or WEEV and was designated Venezuelan equine encephalitis virus (VEEV).

Taxonomy and Classification

In 1954 three serologic groups (A, B and C) of arthropod-borne viruses were distinguished by Casals and Brown on the basis of cross-reactivity in hemagglutination inhibition (HI) tests. EEEV, WEEV and VEEV constituted the original group A arboviruses. A second cross-reacting set, including dengue, St. Louis encephalitis and yellow fever viruses, constituted the group B arboviruses and the other viruses, mostly from Brazil, were designated group C viruses. As viruses became classified on the fundamental properties of the virion and genome, the group A viruses became the alphaviruses (genus *Alphavirus*) within the *Togaviridae* family of enveloped plus-strand RNA viruses. HI classifies alphaviruses into six broad antigenic complexes and EEEV, WEEV, and VEEV form three of these complexes. Viruses within each complex have been subtyped using reactivity with monoclonal antibodies, kinetic HI or neutralization assays. The EEE complex includes Madariaga virus (MADV) as well as EEEV. The WEE complex includes Aura, Fort Morgan, Highlands J, Sindbis, Trocara and Whataroa viruses in addition to WEEV. The VEE complex includes Cabassou, Everglades, Mosso das Pedras, Mucambo, Pixuna, Rio Negro and Tonate in addition to VEEV. WEEV and VEEV can also be subdivided into epizootic and enzootic strains. Epizootic strains of VEEV are equine-virulent and are further subdivided antigenically into subtypes IAB and IC (epizootic strains) and ID, IE, and IF (enzootic strains). Sequence information, has confirmed the validity of most of these serologic distinctions.

Virion and Genome Structure

Properties of the Virion

Alphavirus virions are 60–65 nm in diameter. The RNA is enclosed in a capsid formed by a single protein arranged as an icosahedron. The nucleocapsid is enclosed in a lipid envelope derived from the host cell plasma membrane that contains the viral-encoded glycoproteins, E1 and E2. These proteins form heterodimers that are grouped as trimers to form knobs on the virion surface arranged with a $T = 4$ symmetry. Glycoproteins are arranged with 240 copies of each protein interacting with 240 copies of capsid protein (Fig. 1). The virion is sensitive to ether and detergent. Infectivity can be inactivated by heat or acid. The viruses are stable at -70°C for long periods.

Properties of the Genome

The 49S genome is a nonsegmented, capped and polyadenylated message-sense RNA that is infectious. Complete sequence information is available for representative members of all antigenic complexes. The genomes contain approximately 11,700

Fig. 1 Cryo-EM structure of eastern equine encephalitis virus showing radially colored surface representation. The right half shows a section of the map with the lipid bilayer indicated between the black dotted lines. From Hasan, S.S., Sun, C., Kim, A.S., *et al.*, 2018. nucleotides and have two open reading frames. The nonstructural proteins (nsPs) are encoded at the 5'-end and the structural proteins at the 3'-end. The 3' untranslated region (UTR) is important for negative-strand synthesis, the 5' UTR for genome synthesis and 21 nucleotides at the junction between the nonstructural and structural genes, for synthesis of the subgenomic RNA. Analysis of codon usage shows an underutilization of the dinucleotide CpG.

Properties of the Viral Proteins

Nonstructural proteins

The 5' end of the genome encodes four nsPs that function in replication of viral RNA and in production of the genomic and subgenomic RNAs. The nsPs are translated as a polyprotein from the genomic RNA and sequentially processed to individual proteins by the papain-like protease in the C-terminal portion of nsP2. nsP1 has methyl transferase and guanylyl transferase activities, is palmitoylated and binds the replication complex to membranes. The N-terminal domain of nsP2 has helicase, ATPase, GTPase, methyl transferase and 5'-triphosphatase activity. nsP3 is a phosphoprotein that induces membrane remodeling for the formation of cytoplasmic vacuoles and regulates RNA synthesis in a cell-type-dependent manner. nsP3 has a highly conserved N-terminal macrodomain, a middle zinc-binding region and a poorly conserved, unstructured, acidic and highly phosphorylated C-terminal hypervariable domain that interacts with many cellular proteins to regulate viral replication and assembly of stress granules. nsP4 is the RNA-dependent-RNA polymerase (RdRp).

Structural proteins

Five structural proteins (C, E3, E2, 6K and E1) are translated as a polyprotein from the subgenomic RNA and a sixth small transframe (TF) protein is produced as the result of ribosomal frameshifting. The capsid protein is 259 (EEEV, WEEV) to 275 (VEEV) amino acids long. The N-terminal portion is conserved, basic and binds the genomic RNA and the C-terminal portion interacts with the cytoplasmic tail of E2 and with other capsid proteins to form the nucleocapsid. Capsid also inhibits host gene expression. The E3 protein is 59 (VEEV), 60 (WEEV) or 63 (EEEV) amino acids long, serves as a signal sequence for E2 and, *in vitro*, is shed into the supernatant fluid after cleavage by a furin-like protease in the trans Golgi network. The E2 glycoprotein is a transmembrane protein that is 420 (EEEV) to 423 (WEEV, VEEV) amino acids long and has two (EEEV) or three (WEEV, VEEV) N-linked glycosylation sites. The intracytoplasmic portion has a second stretch of hydrophobic amino acids. The 6K protein is 55 (WEEV, VEEV) or 56 (EEEV) amino acids long, serves as a signal peptide for E1, can form ion channels, remains with interior membranes, interacts with viral glycoproteins and facilitates virus budding. The E1 protein is 439 (WEEV), 441 (EEEV) or 442 (VEEV) amino acids long and has one or two N-linked glycosylation sites. E1 has a short (one or two residue) intracytoplasmic tail and a positionally conserved internal hydrophobic stretch of amino acids in the N-terminal portion of the protein that serves as

Fig. 2 Replication of new world alphaviruses. Genome is message from which nsPs are translated followed by synthesis of full-length negative sense genomic RNA by P123 + nsP4 (early replicase) and formation of spherules with dsRNA, a step dependent on host FXR. P123 processed to individual nsPs forms the stable plus-strand late replicase and synthesis of genomic and subgenomic RNA. Structural proteins are translated from subgenomic RNA.

the fusion peptide for virion entry into the cell. TF is 70 (VEEV), 72 (WEEV) or 92 (EEEV) amino acids long, palmitoylated, trafficks to the plasma membrane and small amounts are incorporated into virions. Ribosomal frameshifting that leads to TF protein synthesis (<30% of the time) eliminates E1 synthesis.

Replication

Initial attachment of virus to the cell likely involves interaction of the E1 glycoprotein, which has hemagglutination activity, with phospholipids on the cell surface. Efficient subsequent entry involves binding of E2 to a variety of cellular proteins followed by receptor-mediated endocytosis. Within the acidified endosomal compartment the glycoprotein spikes undergo a conformational change that results in fusion with the endosomal membrane and release of the nucleocapsid into the cytoplasm. Acidified endosomes may not be essential for infection of mosquito cells. Once released from the nucleocapsid by interaction with ribosomes, the virion genomic RNA serves as mRNA and translation of the nsPs as 2 polyproteins (P123 and P1234) is initiated (**Fig. 2**). Sequential polyprotein processing regulates the synthesis of minus strand full-length template RNA and plus strand genomic and subgenomic RNAs. nsP4 is first cleaved from P1234 and the resulting P123 polyprotein and nsP4 initiate formation of short-lived early replication complexes within spherules at the plasma membrane that synthesize a genome-length minus-strand template viral RNA. Formation of replication complexes requires interaction of the hypervariable domain of nsP3 with host proteins including members of the fragile X syndrome family of RNA-binding proteins. As P123 is processed to the individual nsPs, these complexes convert to stable replication complexes that synthesize plus-strand 49S genomic and 26S subgenomic RNAs within cytopathic vacuoles.

The 26S RNA represents the 3' portion of the genome from which the structural proteins are translated as a polyprotein despite cessation of host protein synthesis. After translation of the capsid protein is complete, it is autocatalytically cleaved from the nascent chain. pE2 (precursor: E3 plus E2) and E1 are transported into the endoplasmic reticulum, cleaved by cellular signal peptidases and processed through the Golgi with a final processing of pE2 into E2 and E3 by furin. At the plasma membrane nucleocapsids align with regions containing the E1-E2 heterodimers and bud from the cell surface. The process may be different in mosquito cells, where intracytoplasmic compartments containing mature virions are seen *in vitro*. However, these structures have not been seen during ultrastructural studies of alphavirus infection in mosquitoes.

Geographic and Seasonal Distribution

The encephalitic alphaviruses are transmitted primarily by mosquitoes during the warm months of the year and geographically restricted. EEEV is endemic in eastern Canada and from New Hampshire along the Atlantic seaboard and Gulf Coast to Texas in the

United States and in the Caribbean. Inland foci exist around the Great Lakes. Recently EEEV has been detected as far north as Nova Scotia suggesting a northward expansion. In the northern part of the range, cases occur between July and October, while in the southern region cases can occur throughout the year. It is likely that EEEV is periodically reintroduced into northern regions from areas of year-round transmission by migratory birds or wind-borne mosquitoes. Three antigenic subtypes of MADV (formerly South American EEEV) are enzootic in the Amazon River basin, the coasts of South and Central America and Brazil with the cycle maintained in moist forests.

Viruses of the WEE complex are widely distributed throughout the Americas as three closely related but antigenically distinct viruses (WEEV, HJV and Fort Morgan virus). HJV is endemic on the East Coast of the United States in the same areas as EEEV. WEEV is widely distributed in the western plains and valleys of the United States and Canada and is found in South America.

Enzootic VEEVs are perennially active in subtropical and tropical areas of the Americas (subtype II in Florida; ID and IE in Central America; IF and III-VI in South America). Epizootics have appeared in Venezuela, Colombia, Peru and Ecuador at approximately 10-year intervals.

Host Range and Virus Propagation

The life cycle of the encephalitic alphaviruses involves replication in invertebrate vectors, primarily mosquitoes, and in reservoir vertebrate hosts, primarily birds (EEEV and WEEV) or small mammals (VEEV). In epidemic periods additional hosts, such as horses and humans, are infected. EEEV causes encephalitis in humans, horses, emus, pigeons and pheasants. Other birds are susceptible to infection but remain asymptomatic, despite prolonged viremia. The amplifying species for EEEV in North America are wading birds and migratory songbirds. Infection has also been reported in turtles and snakes. In South America, forest-dwelling rodents and marsupials are likely reservoirs for MADV. In invertebrates, EEEV is most consistently recovered from the *Culiseta melanura* in North America and *Culex taeniopus* in the Caribbean with MADV recovered from *Cx. (Melanconion)* spp. in South America. Outbreaks of EEE are initiated when the virus spreads from the enzootic cycle involving ornithophilic mosquitoes (*e.g.*, *Cs. melanura*) into mosquito populations that feed on a wider variety of hosts. Mosquitoes of many species can serve as bridge vectors to humans and equids.

WEEV causes encephalitis in horses and humans, but disease is now rare. The enzootic cycle in North America involves domestic and wild birds and *Cx. tarsalis* for WEEV in the western United States and songbirds and *Culiseta melanura* for HJV in the eastern United States. Serosurveys and virus isolations have demonstrated evidence of natural infection in chickens and other domestic birds, passerine birds, pheasants, rodents, rabbits, ungulates and snakes.

Epizootic strains of VEEV can cause disease in horses and in humans. Infection of horses with enzootic strains of VEEV is asymptomatic and may immunize horses for protection against epizootic strains. Enzootic strains produce mild disease in humans. A variety of wild birds are susceptible to infection, but small mammals serve as an important reservoir, with efficient transmission of infection by *Cx. (Melanconion)* mosquitoes.

In addition to the native hosts, a number of laboratory animals are susceptible to infection. All three viruses cause encephalitis in monkeys, mice, rats, guinea pigs and hamsters. Disease is generally age-dependent, so that young animals more often develop fatal infections than do adult animals. Because of this susceptibility primary isolates of these viruses have often been made in newborn mice.

In vitro, the viruses are routinely propagated in cultures of chick embryo fibroblasts, BHK-21 cells or Vero cells. Most strains will form plaques in these cells and plaque assays provide the usual basis for virus quantification. Mosquito cell lines support replication, often without cytopathic effect. Many other cell lines (*e.g.*, L cells, HeLa cells) support replication as well.

Genetics

Alphaviruses show genetic changes by accumulation of point mutations in the genomic RNA, but this occurs at a rate that is slower than that predicted for other RNA viruses. Recombination is infrequent, but can be demonstrated *in vitro* and occurs at least occasionally in nature because WEEV is the result of recombination between EEEV and Sindbis-like viruses.

Evolution

The alphaviruses derive from a single unknown protoalphavirus and viruses in the alphavirus superfamily have a similar genetic organization and include many RNA plant viruses. In general, amino acids important in secondary structure (*e.g.*, cysteine) have been conserved for the structural glycoproteins E1 and E2 consistent with the similar three-dimensional structure of all alphaviruses. Sequence analyses suggest that the encephalitic alphaviruses evolve slowly in nature. The capsid protein and E1 glycoprotein are the most conserved of the structural proteins, whereas the E2 glycoprotein is more divergent.

EEEV has evolved independently in North and South America over the last 1000 years and there is currently one group in North America and the Caribbean and three groups in South America. Based on sequence divergence, as well as ecologic and pathogenesis distinctions the three South American lineages were recently classified as a different alphavirus species MADV. North

Fig. 3 Numbers of human cases of Eastern equine encephalitis reported in the United States from 1964 to 2019. Data are from the US Centers for Disease Control and Prevention.

American EEEV isolates are highly conserved, varying by less than 3% over 100 years consistent with birds as the reservoir hosts. MADV isolates are evolving more rapidly, consistent with small mammals as the reservoir hosts. Rates of divergence of WEEV and HJV of 0.1%–0.2% per year have been estimated. It is hypothesized that short transmission seasons and limited host mobility constrain genetic diversity in a geographic region.

Epidemiology

EEEV causes localized outbreaks of equine, emu, pheasant and human encephalitis in the summers. Cases of equine encephalitis are usually the first indicators of an outbreak. In North America the primary enzootic cycle is maintained in shaded freshwater swamps where the vector is the ornithophilic swamp mosquito *Culiseta melanura* and the reservoir hosts are migratory passerine songbirds. Young birds are probably most important for virus amplification because they are more susceptible to infection, have a prolonged viremia and are less defensive towards mosquitoes. Human and equine cases usually occur within 5 miles of the swamp, with virus being transmitted by epizootic vectors such as *Coquillettidia perturbans*, *Aedes sollicitans*, and, potentially, *Aedes albopictus*. The enzootic vector in the Caribbean is probably *Culex taeniopus* and for MADV in South America is probably *Culex (Melanoconion)* spp. Epizootics appear approximately every 5–10 years and are usually associated with heavy rainfall that increases the populations of enzootic and epizootic mosquito vectors. There is no evidence for overwintering in mosquitoes so the mechanism for maintenance in northern areas is not known and may require reintroduction from southern areas of transmission. Human infections are unusual, with an average of 5–10 cases per year in the United States (Fig. 3). Serological surveys in the northeastern United States suggest that there are approximately 23 inapparent infections for every case of encephalitis, but children are more susceptible and this declines to only 8:1 for children under 4 years of age.

WEEV is maintained in an endemic cycle involving domestic and passerine birds and *Culex tarsalis*, a mosquito particularly adapted to irrigated agricultural areas. Interseasonal persistence occurs in saltwater marshes, where vertical transmission of WEEV in *Cx. tarsalis* has been demonstrated. Occasional isolations have been made from *Cx. stigmatosoma*, *Aedes melanion* and *Ae. dorsalis*, also competent vectors. Transmission from this enzootic cycle has resulted in small numbers of cases of encephalitis in humans. In the past, there have been widespread summer epizootics of equine encephalitis in North America with significant extension into humans. The estimated case to infection ratio is 1:58 in children under five years and 1:1150 in adults. Recently, for reasons that are not completely clear, cases of equine and human encephalitis have declined with the last human case in 1998 (Fig. 4). In the eastern United States, HJV has been isolated from ornithophilic mosquitoes (*Culiseta melanura*, the enzootic vector for EEEV) in freshwater swamp habitats along the Atlantic coast, as well as from birds. HJV can occasionally cause encephalitis in horses and is a recognized pathogen for turkeys, pheasants, emus and whooping cranes. The lack of significant human disease during equine outbreaks of WEE in South America may be related to the feeding habits of the vector or to a difference in virulence for humans of the South American strains.

VEEV is maintained in enzootic cycles by *Culex (Melanoconion)* spp. mosquitoes that live in tropical and subtropical swamps throughout the Americas and breed near aquatic plants. They feed at dawn and dusk on a wide variety of rodents, birds and other vertebrates. Humans living in these areas have a high prevalence of antibody, but little recognized disease. Epizootic strains of VEEV arise by mutation from enzootic strains and are isolated only during outbreaks. Epizootics have occurred primarily in Latin America in cattle ranching areas during the rainy season. Formalin-inactivated vaccines containing residual live virus are suspected to be responsible for initiating the 1969–72 outbreak in Central America that extended to Texas. During epizootics equids are important amplifying species. Virus has been isolated from several species of mosquitoes including *Aedes taeniorhynchus*, *Ae.*

Fig. 4 Numbers of human cases of Western equine encephalitis reported in the United States from 1964 to 2019. Data are from the US Centers for Disease Control and Prevention.

aegypti, *Mansonia dubitans* and *Psorophora confinnis*. The incidence of encephalitis in clinically ill humans is generally less than 5% and the overall mortality less than 1%.

Transmission and Tissue Tropism

The primary mode of alphavirus transmission to birds and mammals is through the bite of an infected mosquito that inoculates virus extravascularly. Mosquitoes become infected by feeding on a viremic host, are able to transmit the virus 4–10 days later (extrinsic incubation) and remain persistently infected. Maintenance of this cycle requires an amplifying host that develops a viremia of sufficient magnitude to infect mosquitoes feeding on it. Other modes of transmission are of occasional importance. EEEV persists in the feather follicles of infected pheasants and secondary transmission among penned pheasants can occur through feather picking and cannibalism. VEEV can be transmitted by the respiratory route between infected horses and to humans in the laboratory. WEEV and VEEV can be transmitted transplacentally.

In mammals, EEEV replicates primarily in muscle and in neurons and glial cells of the CNS, with occasional involvement of liver and lymphatic tissue. Skeletal and myocardial muscle and the CNS of infected birds contain virus. In mosquitoes there is infection of the midgut, muscle and salivary glands without involving the nervous system. WEEV replicates primarily in skeletal and cardiac muscle, brown fat and the choroid plexus, ependyma and neurons in the CNS of mammals. Little is known of the tissue tropism of WEEV in birds. Epizootic strains of VEEV infect the upper respiratory tract, lymphatic and myeloid tissue, pancreas, liver and CNS to varying degrees in different mammals. Mosquito infection is initiated in the midgut epithelial cells and spreads through the hemolymph to the salivary glands and flight muscles.

Pathogenicity

EEEV is the most virulent of the alphaviruses, causing severe encephalitis in humans, horses, dogs, pigs, pigeons, emus, quail and pheasants. The case-fatality rate in humans is 30%–50%, up to 90% in horses and 50%–70% in pheasants. Laboratory studies indicate a similar neurovirulence of EEEV for monkeys, mice and hamsters. Hamsters also develop hepatitis and lymphatic organ infection. At 3–4 weeks of age mice become relatively resistant to peripheral, but not intracranial, inoculation. Birds vary in their susceptibility, with birds of some species developing disease, while birds of many other species show no morbidity or mortality, despite a prolonged viremia. Pheasant deaths are caused by encephalitis while young chickens develop myocarditis. MADV is much less virulent, but infection with lineage III viruses has been associated with cases of fever and encephalitis. Mosquitoes develop persistent infection of the fat body and salivary glands.

WEEV in the western United States caused epidemics of encephalitis in humans, horses and emus, but the case-fatality rate of 10% for humans, 20%–40% for horses and 10% for emus is lower than for EEEV in the eastern U.S. HJV has been rarely reported to cause fatal disease in horses and turkeys. South American strains of WEEV cause fatal encephalitis in horses, but little disease in humans. Epizootic strains are neurovirulent and neuroinvasive in adult mice, whereas enzootic strains are not. HJV is intermediate in virulence between North and South American strains of WEEV. With increasing age mice become relatively resistant to fatal HJV infection, whereas hamsters remain susceptible.

Infection of horses with epizootic strains of VEEV frequently causes fatal disease associated with leukopenia and a high-titered, prolonged viremia. In contrast to EEE and WEE, encephalitis is not always apparent and virus is shed in nasal, eye and mouth

secretions as well as in urine and milk. Experimental infection of laboratory animals produces a variety of disease patterns. In guinea pigs and rabbits, VEEV causes necrosis in lymph nodes, spleen, thymus, intestinal and conjunctival lymphoid tissue, liver and bone marrow. Hamsters develop encephalitis and pancreatitis in addition to widespread infection of myeloid and lymphoid tissues. In rats and mice there is more limited destruction of lymphoid and myeloid tissue and death is usually due to encephalitis. Virus enters the CNS through the olfactory tract and causes neuronal infection and apoptosis. Neonatal mice show extensive replication in many tissues, including brain, myocardium and pancreas. Comparative studies of the virulent Trinidad donkey and avirulent TC-83 strains of IA serotype VEEV and construction of recombinant viruses have led to identification of the 5' noncoding region and the E2 envelope glycoprotein as important determinants of virulence for mice, whereas changes in nsP3 and E2 determine virulence for horses.

Clinical Features of Infection

EEEV is the most virulent of the encephalitic alphaviruses, causing a high mortality due to encephalitis. Prodromal symptoms of fever, headache and myalgias are common. The onset of encephalitis tends to be fulminant and is associated with continued fever, increased headache, meningismus, obtundation and seizures. The overall case-fatality rate is 30% in recent studies, with higher rates in children and the elderly. Recovery is more likely in individuals that have a long (5–7 day) prodrome and do not develop coma. Sequelae are common, with more than 80% of survivors having significant neurological residua, including paralysis, seizures and cognitive deficits. The diagnosis is usually made by detection of antibody in serum or cerebrospinal fluid.

WEEV can cause encephalitis with signs and symptoms similar to those caused by EEEV. There is a 3–5 day prodrome of fever and headache that may progress to irritability, nuchal rigidity, photophobia and altered mental status. Severe disease, seizures, fatal encephalitis and significant sequelae are more likely to occur in infants and in young children.

Infection with epizootic strains of VEEV usually causes relatively mild disease in humans. Illness in adults typically is manifested by fever, headache, myalgias and pharyngitis 2–5 days after exposure. Severe disease, including fulminant reticuloendothelial infection and encephalitis may occur in young children. Children recovering from encephalitis may be left with neurological deficits. Fetal abnormalities and spontaneous abortions may occur with infection during pregnancy.

The cerebrospinal fluid during alphavirus encephalitis usually shows a moderate (up to 4000 cells/mm³) pleocytosis with predominance of either polymorphonuclear or mononuclear cells. Protein is usually elevated and the glucose is normal. The electroencephalogram and magnetic resonance imaging scans are often abnormal, but computed tomographic scans may be normal or indicative only of edema.

Pathology and Histopathology

Initial CNS infection with EEEV in experimental animals is of the capillary endothelial or choroid plexus epithelial cells and spread within the CNS can be cell to cell or through cerebrospinal fluid. The targeted cell within the CNS is the neuron and damage to this cell may be severe and irreversible. Histopathology demonstrates a diffuse meningoencephalitis with widespread neuronal destruction, neuronophagia, gliosis and perivascular inflammation, with polymorphonuclear and mononuclear leukocytes early, and vasculitis and vessel occlusion late. Hamsters also exhibit necrosis of hepatocytes and lymphatic tissue accompanied by local infiltration of mononuclear leukocytes. Initial infection of mosquitoes is of midgut epithelial cells. Infection is facilitated when virus in the serum is concentrated next to these cells as the infected blood meal clots. Infected midgut epithelial cells subsequently degenerate and slough and this process may facilitate penetration of the virus into the hemocoel and rapid dissemination of the infection.

Pathological examination of brains from fatal human cases of WEE demonstrates early perivascular extravasation of blood followed by endothelial hyperplasia, perivascular mononuclear and polymorphonuclear inflammation and parenchymal necrosis. Areas of neuronal degeneration, glial nodules and demyelination are found. Neonatal mice develop acute inflammation and necrosis in skeletal and smooth muscle, cartilage and bone marrow. In animals with encephalitis, the brain shows multifocal areas of necrosis and widespread lymphocytic infiltration of the leptomeninges and perivascular regions of the brain parenchyma. The heart shows a necrotizing, inflammatory myocarditis. Infiltration of mononuclear leukocytes into areas of lung, liver and brown fat also occurs.

The pathology of VEE in horses includes cellular depletion of bone marrow, spleen and lymph nodes, pancreatic necrosis and, in cases with encephalitis, swelling of vascular endothelial cells, edema and mononuclear cell cuffing of cerebral vessels and meningitis followed by the later appearance of demyelinating lesions. Small mammals with widespread involvement of the reticuloendothelial system may develop ileal necrosis.

Both innate and adaptive immune responses are induced by infection. Interferon α/β is produced quickly and virus-specific IgM is often detectable by enzyme immunoassay or neutralization assay very early after onset of the disease. IgM in either serum or cerebrospinal fluid provides a means for rapid diagnosis of infection. IgG antibody appears 10–14 days after disease onset and can be measured by enzyme immunoassay, HI or neutralization. Many lines of evidence suggest that recovery from infection is primarily dependent on the antibody response. Extensive experimental studies to define the antibody specificity and the mechanisms of recovery and protection have been done using infection of mice. Neutralizing and nonneutralizing antibodies against multiple epitopes on the E1, E2 and E3 glycoproteins can protect against challenge and promote recovery.

Cellular immunity has received more limited study, but virus-specific lymphoproliferative and cytotoxic responses have been documented and a mononuclear inflammatory response is common. The importance of cellular immune responses for recovery or for contribution to fatal disease has not been established but interferon- γ can contribute to virus clearance from the CNS. Prior infection with VEEV increases subsequent antibody responses to unrelated antigens. Anti-thymocyte globulin extends time to death in mice infected with VEEV, suggesting a T cell-mediated immunopathogenic component to fatal disease.

Prevention, Treatment and Control

Prevention of infection relies on efforts to control mosquito populations by spraying and reduction of breeding places. Individual use of protective measures such as mosquito repellents and protective clothing are important. Vaccines against EEEV, WEEV and VEEV are available for horses and against EEEV for birds. Experimental human vaccines against EEEV, WEEV and VEEV also are available for laboratory workers exposed to these agents. Most of these vaccines consist of formalin-inactivated virus, but TC-83 is a successful live attenuated vaccine against VEEV for use in horses. TC-83 is also used as a vaccine for humans, although side effects are common. No antiviral agents are of proven usefulness, but supportive treatment of these infections is important.

Future

Construction of full-length cDNA alphavirus clones that can be transcribed into infectious RNA has provided important tools for understanding the functions of various genes and their importance for replication and virulence in the multiple hosts necessary for maintenance of these viruses in their natural cycles. The structures of each of the viral proteins both as individual proteins and polyproteins are needed for interpretation of much of the sequence and virulence data that has been acquired. Further information on the roles of host cell proteins and cell-type dependent differences in replication are likely to provide the next level of understanding of virus-host relationships. There is an ongoing need to develop effective vaccines and therapies.

Glossary

Human virome The total collection of viral nucleic acids, both RNA and DNA, that make up the viral community in and on the human body.

Immunosuppression Partial or complete suppression of the immune response of an individual.

MicroRNA A small non-coding RNA molecule that regulates gene expression by sequestering the messenger RNA (mRNA) and interfering with translation of the mRNA into proteins.

Representational difference analysis Molecular technique used to identify and characterize differences between two complex genomes.

Viral species A monophyletic group of viruses the properties of which are unique and can be distinguished from those of other species by multiple criteria.

Viremia The presence of viruses in the blood.

Introduction

Anelloviruses (AV) are a large group of agents discovered in recent years that infect humans and various animal species. The first indication of their existence was in 1997 when a Japanese team applied representational difference analysis to search for novel hepatotropic viruses in the blood of patients with cryptogenetic post-transfusion hepatitis. They found a novel virus with a particularly small genome formed by a circular single-stranded DNA of negative polarity. This new virus was initially believed a novel hepatitis virus and named TT virus (TTV) after the initials of the first patient in whom it was identified. The significance of TTV was then changed in 2004 when it became the acronym of Torquetenovirus (from the Latin words *torques* and *tenuis*, meaning necklace and thin, respectively) to comply with the International Committee on Taxonomy of Viruses (ICTV) rule stating that no official virus designation shall be derived from people's names. The discovery of TTV also opened a Pandora's box of new and novel roles for viruses. Soon after its identification, it became clear that TTV was neither associated to hepatitis nor to any known disease, as the virus was found to be widespread in healthy and sick people. In the 2000s, the discovery of TTV was followed by identification of numerous related, previously unrecognized viruses, detected in diseased and healthy individuals and with genome properties resembling, yet sometime quite divergent from, those of TTV. Furthermore, polymerase chain reaction (PCR) testing of some blood donors yielded amplicons much shorter than expected for a *bona fide* TTV. Further analyses demonstrated the existence of additional viruses clearly related to but with a smaller genome than TTV. Those groups of viruses were named Torquetenominivirus (TTMV), and Torquetenomidivirus (TTMVD). Since 2009, all of these viruses are classified in the newly established family Anelloviridae (from *anellos*, Latin for ring, to indicate the circular genome) (Fig. 1).

Although knowledge on TTV and related AV has accumulated rapidly, many fundamental aspects of their infection remain unresolved. AV have been found to be amazingly widespread, with abundant viral DNA detectable in the plasma of 80% or more of worldwide general population, but their significance for human health is still unknown. It has been proposed that AV should be considered completely nonpathogenic and recent evidence showing that they represent the most abundant members of the human virome speak in favor of this hypothesis. However, at this time, it seems wiser to consider AV a "disease orphan", similar to other viruses that were found to produce significant pathologies many years after their discovery.

Classification

Initially, AV were classified within the Circoviridae family. This grouping was based on the high genome relatedness between AV and the chicken anemia virus (CAV), a prototype circovirus that causes severe damage to the poultry industry, and from the assumption that all known vertebrate viruses with small circular, single-stranded DNA genomes were circoviruses. Subsequent deeper sequence analysis of AV genomes showed that, although they share many genetic features with the circoviruses, they differed considerably from other viruses of this family (e.g., porcine circovirus, beak and feather disease virus of parrots) and had no major sequence homology. Recognition of these differences and other unique attributes have led to group AV in the Anelloviridae, a family coined *ad hoc* by the ICTV.

The progressive discovery of AV human and animal strains exhibiting genomes highly divergent and with size ranging from ~2 kb to ~4 kb, makes reliable phylogenetic and taxonomic analyses of full-length sequences complicated. From this standpoint, nucleotide sequencing and genetic analysis of the entire open reading frame-1 (ORF1) is the most convenient approach for

Fig. 1 Phylogenetic tree based on full-length nucleotide sequences of viral species of Anelloviridae.

classifying AV, which are grouped in genera, species and isolates to cover their wide range of genetic variability. Based on the currently available data, AV are divided into 12 genera, each of which is designated by a letter of the Greek alphabet with the only exception of the genus *Gyrovirus*, that has been recently moved from Circoviridae to Anelloviridae (Table 1). Within a given genus, the ORF1 DNA genomes of all members have more than 56% divergence with AV of other genera. A species is designated for those AV within a given genus that share 45%–80% identity, while a viral isolate within a species has more than 80% identity with other isolates within the species. By using these criteria, human AV are clustered among 3 of the genera: *Alphatorquevirus* (identifying the TTV sequences) *Betatorquevirus* (TTMV sequences), and *Gammatorquevirus* (TTMDV sequences); the remaining 9 genera include animal AV only. Human TTV sequences are genetically classified in at least 29 major species, each of which consists of numerous isolates. TTMV and TTMDV has been investigated in less detail, and existing data indicate that they may be more homogeneous compared to TTV, but the recognition of much more diversity is expected as the number of available sequences increases.

Virion Structure and Genome

Knowledge of physical-chemical properties of AV is incomplete and has been obtained by studying plasma and, less commonly, fecal extracts of TTV infected individuals. As determined by PCR analysis of infected serum passed through polycarbonate filters of decreasing pore size, the TTV particle is approximately spherical and has a diameter of between 30 and 32 nm (below 30 nm for TTMV). Isopycnic density was found to be 1.32–1.33 g/ml in cesium chloride (1.27–1.28 g/cm³ for TTMV) and 1.26 g/ml in sucrose gradients. Because

Table 1 List of genera and species in the family of Anelloviridae

Family	Genus	No. of species included	Representative species
Anelloviridae	<i>Alphatorquevirus</i>	29	Human torquetenovirus
	<i>Betatorquevirus</i>	12	Human torquetenominivirus
	<i>Deltatorquevirus</i>	1	Torque teno tupaia virus
	<i>Epsilontorquevirus</i>	1	Torque teno tamarin virus
	<i>Etatorquevirus</i>	2	Torque teno felis virus
	<i>Gammatorquevirus</i>	15	Human torquetenomidivirus
	<i>Gyrovirus</i>	1	Chicken anemia virus
	<i>Iotatorquevirus</i>	2	Torque teno sus virus 1
	<i>Kappatorquevirus</i>	2	Torque teno sus virus k2
	<i>Lambdatorquevirus</i>	1	Torque teno zalophus virus

	<i>Zetatorquevirus</i>	1	Torque teno douroucoulis virus
	<i>Unclassified</i>	At least 28	Torque teno rodent virus

density does not change following Tween 80 and is poorly affected by solvent/detergent treatments, TTV has been deduced lack an external lipid envelope and to be as stable to inactivation by chemical and physical agents as parvoviruses and circoviruses.

The component of AV currently best understood is the genome. Early characterization showed that nucleic acids extracted from TTV were sensitive to DNase I and mung bean nuclease but resistant to RNase A and specific restriction enzymes, indicating that the viral genome is single-stranded DNA. Initially, when the prototype Japanese isolate TA278 was sequenced to about 90%, it was proposed that the genome was linear. When sequencing of TA278 genome was further extended, it was then recognized that the two extremities were connected by a guanine and cytosine (GC)-rich stretch of about 100 nucleotides (nt), that was hard to amplify and sequence in earlier studies and that completes the covalently closed circular molecule. Hybridization/nuclease protection assays also showed that virions encapsidate the minus strand.

The genomes of many of the human and animal AV have been sequenced in their entirety, and show similar genomic organization. However, although all consist of a circular molecule of single-stranded DNA, AV genomes differ in size; TTV is 3.5–3.9 kilobases (Kb), TTMDV around 3.2 Kb, and TTMV 2.7–2.9 Kb. All are negative sense, contain an untranslated region (UTR) of about 1.2 kb, and a potential coding region of approximately 2.6 kb. The UTR appears to control virus replication and expression through a number of important regulatory sequences and secondary structures (those formed by the 100 nt high GC region are particularly important), and it possess a short nucleotide sequence highly conserved among all AV isolates. The coding region consists of two major potential protein-coding genes, named ORF1 and ORF2. These ORFs are of different size, are present in the plus strand complementary to the genomic DNA, partially overlap and are in different reading frames. In the prototype TA278 sequence, ORF1 spans nt 589–2898 and ORF2 spans nt 107–712, which correspond to a coding capacity of 770 and 150 amino acid (aa), respectively. The length of the two ORFs may vary in individual isolates. ORF1 is believed to encode the putative capsid protein, which also contains specific motifs: (1) an arginine-rich hydrophobic region at the N-terminus that is believed to mediate binding of the genome to the capsid and its transportation to the cell nucleus; (2) a hypervariable region (HVR) located centrally that encodes potential glycosylation sites that vary in number and location in individual AV strains and that might affect several biological properties of the resulting protein, including antigenic specificity; (3) short aa motifs typical of replication-associated proteins (Rep) of viral DNAs replicating using the rolling circle mechanism. The smaller ORF2 encodes for a putative nonstructural protein of approximately 100–120 aa that is thought to possess phosphatase activity and be involved in viral replication. Sequence analysis of AV isolates predict additional putative ORFs that might encode for proteins which function is poorly characterized. Among these, there are two phosphorylated proteins, one resembles the gene NS5A of hepatitis C virus, the other, named TTV-derived apoptosis-inducing protein (TAIP), has been shown to induce p53-independent apoptosis in various human hepato-cellular carcinoma cell lines at levels comparable with that of CAV apoptin.

Life Cycle

Although the discovery of TTV was over twenty years ago, the AV life cycle is poorly defined. Lack of *in vitro* systems to efficiently cultivate and propagate viral isolates has greatly limited studies of this family of viruses. This includes the screening of cell types supporting replication of AV, the identification of the receptor(s) on the cell surface used for viral entry, the dissection of the biosynthetic machinery exploited to replicate the virus, identification of intracellular signaling pathways perturbed, and visualization of cytopathic effects on infected cells. Our current understanding of AV replication mechanisms is thus mostly based on inference from what is known about other single stranded DNA viruses, even though these have not been studied in great detail either. What is certain about is that AV are found in many organs and infect different cell types. It is presumed, therefore, that the cellular receptor(s) used for viral entry is/are widespread in tissues and exposed by a wide array of cell types. A precise definition of

cell types supporting virus replication is not yet available. Since related single-stranded DNA viruses require actively multiplying cells for productive replication, it is conceivable that replication of most, if not all, AV depends on cellular proteins expressed during the S-phase of cell cycle. It has also been shown that the same cell can be infected with more than one AV, thus explaining why recombination is a frequent occurrence among these viruses.

Transcription analysis of prototype TTV strains have led to the identification of at least three RNA transcripts of different lengths (3.0, 1.2, and 1.0 Kb). Such transcripts share common 5' and 3' termini and are encoded by the positive DNA strand through alternative splicing. However, the transcriptional strategies of different AV vary considerably. The mechanism of DNA replication is not known with certainty but there are several indications pointing to a rolling circle mechanism. Such a mechanism, particularly well-suited for single-stranded DNA viruses, is indicated by the presence in ORF1 of conserved Rep protein motifs typical of the many viruses that replicate in this manner. The absence of motifs typical of known DNA polymerases in the encoded products suggests that the genome is replicated by cellular enzymes. Due to the great genetic diversity of AV, it has also been hypothesized that the viral DNA is replicated by polymerases with poor or no proof-reading activity. Indeed, rates of nucleotide change found in the HVR region of TTV are at least ten-fold higher compared other DNA viruses and are similar to that observed for RNA viruses. Using a combined computational and synthetic approach, microRNA-coding regions have been identified in diverse human TTVs and likely produce TTV microRNA *in vivo*. To this aim, TTV utilizes the host microRNA biogenesis machinery to produce biologically active microRNAs. Although their role in viral replication is unclear, it has been hypothesized that they promote viral persistence and immune evasion.

Modes of virion assembly and release from producer cells are not known. It is likely that virus particles are assembled in the cytoplasm and, in analogy with what observed with other nonenveloped viruses, released by cell lysis. However, recent findings demonstrating that TTV particles are sequestered within circulating extracellular vesicles suggests other routes of egress of progeny virions. Available data do not support the idea that TTV can persist as an episome or is integrated into host cell DNA.

Epidemiology

AV are among the most successful viruses of humans. Indeed, the best documented aspect of AV epidemiology is the remarkably high diffusion of infection in general population and throughout the world. Epidemiological surveys employing PCR assays of high sensitivity and searching UTR or the most conserved segments of encoding regions in the blood, have shown that TTV infects nearly two third of the general population and that prevalence is not related to geographical, socio-economical, and age- and gender-related factors. Interestingly, prevalence is high in geographically segregated populations that have limited contact with the rest of the world. TTMV and TTMDV have a prevalence of active infections similar to TTV, thus individuals who carry multiple AV in their blood and/or other tissues are the rule rather than an exception. Metagenomic analyses provided evidence for the presence of as many as 47 different species of AV in the gut of one infant at 12 months of age. Systematic studies performed using standardized and consistent protocols will allow the proportion of individuals carrying multiple species of TTV to be defined and meaningful comparisons of the study cohorts to be performed.

Although in some surveys viremia rates increase with age and peak in adulthood, AV infection is frequent already in the early months of life. This implies that AV infection is highly contagious and uses various routes of spread. That AV can be transmitted via blood and blood products has been repeatedly documented. Most screenings performed early after TTV discovery found the highest detection rates amongst polytransfused, thalassemic, and long-term hemodialysis patients, as well as hemophiliacs, and intravenous drug abusers, clearly indicating that TTV is a blood-borne virus. These observations, again to comply with ITCV rules, prompted a change of the original TTV acronym from Japanese patient initials to "Transfusion Transmitted Virus". As mentioned above, this denomination was replaced by the current definition as soon as it became evident that TTV viremia rates in general population were far too high to be explained by blood-borne transmission. Indeed, TTV was later found in feces, respiratory secretions, and various biological fluids. The common occurrence of TTV in feces of viremic patients suggests that oral-fecal route is a significant mode of transmission. This finding combined with the high prevalence of virus carriers and a high resistance to physicochemical agents, leading to the presence of the virus in food, wastewater, drinking water, and river water, likely contributes to a particularly high dissemination of TTV in human environment. Attempts are underway to evaluate whether TTV might be useful as a marker of anthropic pollution instead of or in addition to enteric bacteria. Mother-to-fetus transmission of TTV is also very common. TTV DNA sequences similar to those in the corresponding maternal blood were detected in newborns and cord bloods in amounts as high or higher than the respective peripheral blood. Alternative routes of AV spread have been poorly investigated, although TTV and related AV have been detected in nasopharyngeal and genital secretions, suggesting that, at least in some instances, the virus can be transmitted via respiratory and sexual routes. AV DNA sequences are also found in saliva, tears, skin, and hairs implying that household contact transmission is also possible. Whether non-human AV or AV-like viruses, reported to be widespread in chickens, pigs, cats, dogs and other farm and companion animals, contribute to AV epidemiology in humans is unclear. More detailed analysis of these viruses is needed to establish whether animal AV add to the already enormous reservoir of AV genomes existing in nature and contribute to human AV evolution and diversification.

Few studies have investigated the geographical distributions of TTV species. Some species have been found to be very common worldwide, others seem to be less frequent or clustered in specific geographic regions. It is also uncertain whether these data reflect

real differences in species distribution or are biased by preferential amplification of selected species by the molecular assay used. Whether species frequency varies with age of infected subjects and/or route of transmission also remains to be determined. Extensive investigations with next generation sequencing (NGS) or other standardized tools are warranted to obtain a wide and precise epidemiological picture.

Clinical Features

To date, the medical significance of TTV and AV in general is unclear. Undoubtedly, the circumstances in which TTV was discovered greatly influenced initial studies in the attempts to link the virus to a clinical disease. The temporal association between TTV viremia and the elevation of transaminases observed in transfused patients in whom TTV was demonstrated, as well as the apparent ability of TTV to replicate in the liver, led to the suggestion that the virus was a possible cause of acute and chronic liver disease, particularly those that have a putative viral cause but are unrelated to known viruses. Later findings disputed this correlation and, to date, although it cannot be excluded that TTV infection could be occasionally associated with occasional liver injury of varying severity, the virus is no longer considered an important cause of clinically overt liver disease.

Attempts to evaluate the possible role of TTV and other AV in the genesis of extrahepatic illnesses of unknown origin have, therefore, been explored. Given the chronic nature of most if not all TTV infections, most studies have been focused on chronic diseases such as diabetes, cryoglobulinemia, psoriasis, rheumatoid arthritis, systemic lupus erythematosus, Kawasaki syndrome, multiple sclerosis and other neurological diseases for which a viral etiology has long been suspected. In all cases, a direct role of TTV in disease etiology has been excluded or proved inconclusive. Because TTV infection is acquired early in life, other studies were performed to correlate TTV infection with acute pathologies of presumable viral origin occurring in infants. Here, it has been shown that TTV might behave as a respiratory virus and be involved in inducing or aggravating some acute pediatric respiratory diseases in which no other etiological agents were detected. Additional diseases for which a role of TTV has been sought in children are asthma and bronchiectasis. In fact, a correlation between TTV load in nasal fluid and severity of the associated respiratory deficit was observed in both these diseases. Other studies also implicated TTV or TTMV in a few renal ailments and in certain forms of anemia, neutropenia, and thrombocytopenia. However, until final proof of these or other findings, TTV and other AV should be considered “viruses waiting for a disease” or “disease orphans” in the same way that other viruses have been linked to a disease years after their discovery (*e.g.*, echoviruses, reoviruses, Epstein-Barr virus, *etc.*). So far, AV behave exactly as formerly orphan viruses and we are still seeking occasional infections sufficiently aggressive to trigger significant clinical disease. Additionally, it cannot be excluded that only some types of AV are pathogenic but their virulence is blurred by the plethora of non-pathogenic types. An unresolved question is whether AV modulate the host’s adaptive immune response. It has been demonstrated that TTV interacts systematically with many cellular sensors, including those modulating immune and inflammatory responses. Because of the small number of focused studies performed and the limitations of *in vitro* methods, detailed information on the mechanisms involved in AV-cell interactions and pathways involved is lacking. A few studies have showed that TTV ORF2 protein suppressed NFκB activity, which is crucial for expression of many genes connected to inflammation. It has also been shown that the TTV genome, as well as its replicative intermediate in infected cells, may influence the synthesis of pro-inflammatory cytokines evoked following stimulation of Toll-like receptors. Again, different TTV species have been shown to encode microRNAs, which are often sequestered within plasma exosomes of infected individuals. Interestingly, at least one TTV species encodes a microRNA *in vivo* that targets IFN signaling and, therefore, possibly modulates immune evasion by antagonizing the host antiviral response. Overall, these findings support the idea that TTV influences various biological processes and this leads to an elevated inflammatory status that is either generalized or in specific body sites. Further, perturbation of biological processes may be proportional to the type(s) and amount of TTV(s) circulating in the infected host.

From another perspective, put forward following discovery of TTV and its surprisingly high prevalence, the fact that no disease is associated with active infection and that the virus undergoes sustained and continuous replication in healthy individuals has led to the hypothesis that AV is devoid of pathogenic potential. This idea strengthened since initial observations to the point that TTV is now considered integral part of the normal human microflora. Further, TTV can be considered a stepping stone for reconsidering some key aspects of virology. Once thought to be only present in the host during disease, viruses have recently been demonstrated to be numerous in various body sites of healthy subjects, and the term virome has been coined to describe the collection of viral species present in a human organ. This sort of viral “flora” is an ensemble of “innocuous” entities such as bacteriophages, endogenous retroviruses, eukaryotic viruses not associated with diseases, and noxious viruses causing acute, chronic or latent illnesses. Thanks to NGS technology, the human virome has been studied in various compartments, such as respiratory tract, gut, and skin in healthy and sick conditions. To date it is known that some components of human virome are present only in a few areas and few individuals, others are disseminated in almost all body sites of a very high percentage of people. AV, and particularly TTV, are the paradigmatic example of the latter. They are the most representative and abundant viruses of the human virome and their load in plasma is proposed as a simple and general measure of immune system function of infected hosts. In keeping with this notion, it has been shown that TTV viremia increases after autologous hematopoietic stem cell transplantation (HSCT) but returns to pre-HSCT levels once the immune system regains its functionality. Thus, monitoring TTV viremia might prove useful in estimating the time interval between the chemotherapy courses required to minimize the occurrence of opportunistic infections. Again, the immunological status of solid organ transplant recipients and the shape and composition of the virome are closely connected. In transplanted patients, marked expansion of viral species of Anelloviridae family and high titer of virus indicate

Fig. 2 Factors impacting the size of TTV viremia. P, proven; EA, some direct evidence available; H, hypothetical.

Table 2 Dynamic of chronic TTV viremia, relative to other viruses

<i>Virus</i>	<i>Mean virion half-life in plasma</i>	<i>New virions entering plasma per day</i>
Hepatitis B	28.8 h	$> 1.7 \times 10^{13}$
Hepatitis C	2.7 h	$> 1.3 \times 10^{12}$
HIV-1	< 1 h	$> 9.8 \times 10^9$
TTV	4.3 h	$> 2.0 \times 10^{10}$

strong immunosuppression and risks of opportunistic infection. Conversely, a lower-than-average burden of TTV is indicative of insufficient immunosuppression and risk of graft rejection.

Pathogenesis

A well-known feature of AV is the ability to establish, in many if not all exposed individuals, chronic productive infections characterized by continuous and abundant presence of the virus in the bloodstream. The course of infection is mostly unknown and the small amount of information available almost exclusively concerns TTV. Body sites and cell types where AV undergoes primary amplification following body entry as well as tissues sustaining its continuous replication and shedding in blood circulation are unknown. In children hospitalized for acute respiratory infections, higher TTV loads were measured in the nasal secretions compared to blood and, more interestingly and in some individuals, the same viral isolate was detected earlier in nares than bloodstream, suggesting that the respiratory tract is a site of primary TTV amplification. After its entry, TTV becomes detectable in the peripheral blood within one or a few weeks, indicating that dissemination of infection throughout the body is rapid. The most frequent outcome of TTV infection is a prolonged, likely lifelong TTV viremia sustained by genuine or, in a minority of cases, by a mix of viruses acquired through multiple exposures. Cases of self-limited infection have been also reported in which viremia spontaneously disappears a few weeks to several years post-exposure. It is unclear whether this is the result of an eradication of infection, decreased virus shedding into blood and/or increased virus clearance, or an infection entered in a latent inactive state. In chronically infected persons, the levels of plasma TTV vary extensively, ranging between 10^1 to over 10^9 DNA copies per ml. In many individuals, TTV viremia remains essentially stable over time, in others it undergoes wide fluctuations over time under the influence of various factors that may directly or indirectly impact on viremia size (Fig. 2). During replication, TTV is produced in large amounts: in kinetic studies of TTV viremia in patients treated with interferon for concomitant hepatitis C, it has been calculated that 10^{10} TTV virions are generated per day with nearly all virus entirely cleared and replenished in plasma on a daily basis (Table 2).

Remaining aspects of TTV interactions with the infected host are far less well characterized. For instance, the target tissues and organs from which TTV is continuously released into the bloodstream and the fate of cells sustaining viral replication are unknown. Almost all anatomical body sites have been found to harbor variably abundant TTV. These include liver, lung, pancreas,

spleen, kidney, lymph nodes, skeletal muscles, thyroid gland, bone marrow and circulating leukocytes. Only the cerebrospinal fluid is usually virus negative provided that the blood-brain barrier is intact. The presence of double-stranded viral DNA and viral mRNA, *i.e.*, two important cellular markers of TTV replication, has been reported in liver, bone marrow, and circulating peripheral blood mononuclear cells, but the methods to detecting such replicative intermediates have many pitfalls, thus leaving ample room for questioning the findings. Most findings support the idea that proliferating hematopoietic cells are an important source of circulating TTV. The idea is strengthened by the fact that baseline TTV viremia decreased to undetectable levels in patients under myelosuppressive treatments (*e.g.*, cyclophosphamide and total body irradiation) for bone marrow transplantation. Since neither viral receptor nor *in vivo* tropism are known, it cannot be ruled out that other cells sustain TTV replication and that different species of TTV and AV replicate in different cell types, tissues and body compartments. How rapidly and effectively the host immune system restrains an invading AV is also unknown. While nothing is known about anti-TTV cell mediated immune responses, current knowledge about humoral responses suggests that TTV elicits antiviral antibodies that fail to eradicate the virus, at least in the great majority of cases. The frequent identification of people infected by multiple and heterologous TTV species highlights the inability of anti-TTV specific antibodies to clear the virus or protect against subsequent infections. Sequential examination of patients accidentally infected through contaminated blood and of chimpanzees experimentally infected with human AV has shown that the antibody response mounts rather slowly. TTV-specific IgM become detectable in serum 10–21 weeks post-infection, 2–7 weeks after the first detection of TTV DNA in the blood. IgM declined in titer later on to disappear within 5–11 weeks, although longer persistence was reported. IgG antibodies generally developed with a lag of several weeks, increased in titer concomitant with IgM decline, and last with little variation for a prolonged period of time or even indefinitely.

Most if not all the TTV detected by molecular methods in the serum of chronically infected subjects is immunoprecipitated with anti-human IgG sera, indicating that TTV circulate in the blood bound to Ig. Conversely, in individuals with putative acute infections, free TTV particles in blood are abundant and often overwhelm the IgG complexed ones.

Diagnosis

Laboratory diagnosis of AV infection is still at infancy. This is due to the following reasons: (1) there are no reliable and sensitive tissue culture systems for AV isolation and propagation; (2) there are no easy-to-use immunological methods to detect and titrate AV induced antibodies, and this in part accounts for their unclear significance in the course of viral infection; (3) detection of viral antigens in plasma is also unavailable. Diagnosis of infections relies, therefore, on the detection of TTV genome in blood or other specimens. Here too there are some caveats: most PCR assays are incapable of detecting the entire spectrum of AV species, standardization is far from being achieved because each laboratory sets up its own test independently, there have been few inter-laboratory exchanges of methods and molecular constructs and there are no international standards. As a matter of fact, validated, *in-vitro* diagnostic labeled assays to detect and quantitate TTV DNA are badly needed but uncertainties about the clinical relevance of AV infection has discouraged most commercial companies from investing in this field.

Because of great genetic variability of AV, identification of the viral DNA segment to be targeted for amplification dictates the sensitivity and spectrum of viral species detection. This is true in general for all viruses and crucial for AV, where variability is an order of magnitude higher compared to other viruses. Historically, the first PCR protocols were designed to target the TTV ORF1 gene. Soon after their development, however, it became clear that they greatly underestimated the prevalence rates of the infection since PCR primers annealed to poorly conserved sequences. As reported above, sequence homology of the UTR is higher than ORF1 across the different TTV isolates, particularly for a segment that is shorter than 100 nucleotides, making it suitable for developing PCR assays capable of detecting all or nearly all the 29 species currently identified. Indeed, when compared to ORF1-PCRs, UTR-PCRs greatly increased the rates of samples scored positive for TTV DNA. It has however been pointed out that even UTR-PCR assays can be biased towards some species, unless primers are carefully designed. UTR-PCR assays capable of simultaneous detection of all TTMV and TTMDV species have not been developed at the moment.

It is evident that correlation of AV to a specific disease and/or to use the viruses as potential biomarkers of immune function is difficult without precise quantification of the virus. Recently developed real-time PCRs and droplet digital PCRs targeting TTV UTR and measuring the viral content in plasma and other biological samples hold promises to reduce the gap. TTV viremia as determined with UTR-PCRs is 10- to 100-fold higher compared to ORF1-PCRs, reflecting the higher sensitivity of former assays as well as detection of TTV species poorly or not amplified by latter. The lower limits of detection of quantitative PCR assays are on average 10–100 DNA copies per ml of blood, a threshold that is likely sufficient, based on available information and because of the high levels of viremia established for most diagnostic purposes.

TTV genotyping exploits genomic sequences informative for classification and, for this purpose, ORF1 gene is an apt target as it permits grouping of all AV by either sequencing of the whole gene or using genotype-specific primers in standard PCR assays. The concomitant presence of multiple AV, a frequent occurrence in most subjects, is a confounding factor that impairs reliability and applicability of genotyping assays. NGS technology is a valid alternative for precise genotyping.

In the quest for establishing routes of transmission and disease association it is crucial to extend examination to other clinical specimens. TTV DNA has been detected in feces, saliva, nose swabs, throat swabs, and breast milk of viremic subjects. Of note, some biological fluids scored positive also in persons with no detectable viremia.

Treatment and Prevention

As long as their clinical implications remain undefined, there will be little attention paid to the prevention and control of AV infection. It is also clear that, based on knowledge accrued so far, there is little doubt that prevention of infection is extremely difficult in the absence of specific polyvalent vaccines. There are no drugs of proven efficacy for AV infection, and the current lack of information on AV pathogenicity does not justify specific clinical trials. In patients treated with IFN α alone or in association with ribavirin for HBV or HCV infections TTV viremia did not change or decreased only transiently. Antiretroviral drugs have no anti-TTV activity. Specific antivirals are likely to be developed should one day AV infection be considered clinically relevant and worth treating.

Glossary

CAP Methylated guanosine linked to the first nucleotide of the RNA, essential to initiate protein synthesis, protect RNA from the exonuclease cleavage, and recruit protein factors for several functions.

CD4⁺ T-lymphocyte (or T-cell) T-cell identified by the CD4 marker associated to the TCR (T-cell receptor for the antigen), which enables the cell to recognize antigen processed by antigen processing cells (macrophages, monocytes, dendritic cells). After recognition, the T-cell becomes activated and can collaborate with other cells of the immune system, such as B-cells (for antibody production) and other T-cells (for cell-mediated immune responses).

Chemokine Chemotactic molecule which stimulates inflammation. Chemokines are usually produced by the injured tissues, and attract neutrophils, monocytes, macrophages, lymphocytes, dendritic cells, eosinophils, and basophils.

Endogenous lentivirus Lentivirus which infected sexual cells (sperm or ovum) and became part of the germline, being passed from generation to generation throughout thousands or millions of years. Usually endogenous lentiviruses have acquired mutations which avoid them from productive replication (replication deficient).

Enhancer Sequences in the 5' non-coding region of the genome which are recognized by cellular factors and trigger RNA transcription.

Exogenous lentivirus Lentivirus which is transmitted in a contagious manner, either after budding and being recognized by receptors, or by cell-to-cell contact. Usually it is replication competent.

Immunodeficiency State in which the immune system is unable completely or in part to fight infectious disease and cancer.

Lipid rafts Microdomains in the plasma membrane less fluid than the surrounding lipid bilayer, enriched with cholesterol, saturated phospholipids and membrane proteins.

Macrophage Cell derived from blood monocytes, with high phagocytic ability, which resides in tissues. It participates both in the innate and adaptive immunities.

Promoter Region at the 5' end of genes which triggers RNA transcription for protein synthesis.

Provirus DNA genome of retroviruses, after the viral single-stranded RNA is reverse transcribed into double-stranded DNA and integrates in a host chromosome.

Introduction

Lentiviruses are grouped in a genus within the family *Retroviridae*. The name derives from the Latin word *lenti* which means slow, alluding to the long incubation period of the disease, which in most cases lasts years. During this period the virus seems to be controlled by the immune system but steadily replicates and increases in numbers. When the viral load is too high and the damage to the different systems, mainly the immune system, grows unendurable, the disease becomes apparent and the infection turns fatal. The discovery that acquired immune deficiency syndrome (AIDS) was caused by a lentivirus, human immune deficiency virus (HIV), prompted the study of lentiviruses in other species. Up-to-date lentiviruses have been identified to infect humans and other primates, cats, cattle, sheep, goats and horses. Recently lentiviruses have been shown in rabbits and ferrets. Most animal lentiviral infections are notifiable diseases to the World Organization of Animal Health (OIE). All lentiviruses have similar biochemical, morphological and antigenic properties. They share common features regarding virion particle structure, genetics, infection kinetics, tropism, immune response elicited, transmission, etc. In general, lentiviruses infect immune cells (mainly macrophages and T-lymphocytes) and induce several types of immune dysfunctions (macrophage subset differentiation, T-cell anergy, etc.), inflammation, and organ/tissue impairments. As in other retroviral infections, infected cells carry the retroviral genome (provirus) throughout their life and pass the infection to their progeny. Unlike other viruses, lentiviruses may efficiently infect non-dividing cells.

Classification

Genus *Lentivirus* is one of the six genera of the subfamily *Orthoretrovirinae* within the family *Retroviridae*. The genus, that traditionally contained seven members, has recently expanded to 10 after the addition in the 2018 release of the International Committee on Taxonomy of Viruses (ICTV) of Puma lentivirus (PLV), Jembrana disease virus (JDV), and HIV-2. All lentiviruses are genetically related and must have derived from a single ancestor, which has co-evolved with the hosts that originated from the initial one. Thus, lentiviruses may be classified according to the hosts they infect. Primate lentiviruses include human immune deficiency virus (HIV) type 1 (HIV-1) and type 2 (HIV-2), as well as simian immune deficiency virus (SIV), which has been identified in many different non-human primates with genomic differences between them. Small ruminant lentiviruses (SRLV) include visna-maedi virus (VMV) of sheep and

Fig. 1 Phylogenetic tree of the genus *Lentivirus* after alignment. Names of the viruses are shown in [Table 1](#). HIV-1 and HIV-2 are in blue to more easily locate their phylogenetic relationships. RELIK is an endogenous lentivirus found in the rabbit genome.

caprine arthritis encephalitis virus (CAEV) of goats. Cattle lentiviruses had a single representative, bovine immunodeficiency virus (BIV), but as mentioned above, now also the closely related JDV is considered. As of now, lentiviruses of carnivores have been shown to infect felids exclusively and include feline immunodeficiency virus (FIV) and PLV. Lastly, the lentivirus of horses is named equine infectious anemia virus (EIAV) ([Fig. 1](#)). Within the primate lentiviruses, for example, HIV-1 and HIV-2 differ in that the sequences only present no more than 50% homology between them, and that HIV-1 has *vpx* while HIV-2, *vpu*. This reflects that HIV-1 and HIV-2 originated from different ancestors, HIV-1 from chimpanzees and gorillas, and HIV-2 from sooty mangabey. As lentiviruses are genetically related, they have certain cross-reactivity between the Gag proteins, but cross-reactivity is non-existent between proteins codified by the gene *env*. For a long time lentiviruses had been considered to be only exogenous or contagious, but recently the germlines of leporids (rabbits and hares) and ferrets have been shown to carry endogenous lentiviruses, remnants of ancient infections which have lost the ability to produce infectious virions (see below).

Virion Structure

As in the rest of the retroviruses, lentiviral particles are rounded. The size is slightly larger than in other retroviruses, 100–130 nm in diameter; SIV particles can reach even 150 nm in diameter. They are enveloped, with short projections distributed evenly on the envelope, composed of two proteins: surface proteins (SU), the outermost, and transmembrane (TM), which anchors SU to the envelope. Inside the virion electron micrographs reveal a core shaped like a truncated cone or rod, composed of capsid proteins (CA). The matrix proteins (MA) fill the space between the envelope and the core to give consistency to the viral particle. The capsid contains two identical helical nucleocapsids, each consisting of a molecule of RNA, surrounded by the nucleocapsid proteins (NC) and associated with the proteins that are involved in the early stages of viral replication: the protease (PR), reverse transcriptase (RT) and integrase (IN), as well as Nef, Vif and Vpr in the lentiviruses that have them ([Fig. 2](#)).

Genome

Both molecules of single-stranded RNA are identical. They are 7700–11,000 nucleotides (nt) long ([Table 1](#)) and are linked by hydrogen bonds. They have a CAP sequence at the 5' end and a polyadenylated tail around 200 nt long in the 3' end. Regardless of these characteristics, they do not act as mRNA. As in other retroviruses, lentiviruses possess three main genes, *gag* (which encodes the inner proteins), *pol* (which encodes the proteins for replication, protease, reverse transcriptase and integrase) and *env* (which

Table 1 Species of lentiviruses recognized by the International Committee on Taxonomy of Viruses (ICTV) in the 2018 release (https://talk.ictvonline.org/ictv-reports/ictv_9th_report/reverse-transcribing-dna-and-rna-viruses-2011/w/rt_viruses/161/retroviridae). GenBank Accession Numbers of the prototype strains or that corresponds to the complete sequence of the virus, total length of the genome (expressed in nucleotides, nt) and accessory genes present in each species are shown

Virus	Complete name	Abbreviation	GenBank	nt	Accessory genes
Carnivores	Feline immunodeficiency virus	FIV	EU117992	9891	<i>rev response element, vif, orfA</i>
	Puma lentivirus	PLV	NC_038669	9100	<i>vif</i>
Cattle	Bovine immunodeficiency virus	BIV	M32690	8482	<i>tat, vif, rev, vpw, vpy, tmx</i>
	Jembrana disease virus	JDV	NC_001654	7732	<i>tat, rev, vif, tmx, Jdvgp5</i>
Small ruminants	Visna-Maedi Virus	VMV	NC_001452	9202	<i>vif, rev, vpr-like</i>
	Caprine arthritis and encephalitis virus	CAEV	NC_001463	9189	<i>vif, rev, vpr-like</i>
Primates	Human immunodeficiency virus type 1	HIV-1	K02007	9737	<i>tat, rev, vif, vpr, vpu, nef</i>
	Human immunodeficiency virus type 2	HIV-2	NC_001722	10,359	<i>tat, rev, vif, vpr, vpx, nef</i>
	Simian immunodeficiency virus	SIV	KU892415	10,276	<i>tat, rev, vif, vpr, vpx, nef</i>
Horses	Equine infectious anemia virus	EIAV	M16575	8407	<i>tat, rev, S2</i>

encodes the external glycoproteins). Besides these genes, lentiviruses have genes the products of which regulate the synthesis and processing of the viral RNA (*tat* and *rev*), and other accessory genes (*vif*, *vpr*, *vpu*, *nef*, *tmx*, etc.) that play an important role in the viral replication, in counteracting the restriction factors of the host and in pathogenesis (Fig. 3). HIV and SIV are the lentiviruses with the highest number of accessory genes, followed by BIV (Table 1). Several of these accessory genes may have similar functions to other genes with different names in other lentiviral species, so the list may be misleadingly long. For example, BIV has *tat*, *rev*, *vif*, *vpw*, *vpy*, and *tmx* genes, the last three with functions similar to HIV-1 *vpr*, *vpu* and *nef*, but with limited sequence similarity to the human virus counterparts. The role in pathogenesis of several of these genes has not been ascertained unequivocally or they may have several functions carried out by single genes in other lentiviruses. This is the case of FIV *orfA*, which acts by increasing the net translation of viral gene products similar to HIV Tat, but it does not increase transcription or use a Tar element in the same way as Tat. This gene also shares similar functions to *vpu*, *vpr* and *nef* of HIV-1. Animal lentiviruses, except for HIV and primate lentiviruses, also encode a protein involved in regulating cellular dNTP ratios, the viral dUTPase, although BIV encodes a dUTPase-related gene without enzymatic activity.

At each end of the viral RNA there are the same ~ 100 nucleotides, a sequence known as repeat region (R). In addition, at the 5' end there is a unique region about 70 nucleotide long (U5), and at the 3' one of about 450 nucleotides long (U3). These regions are essential to start reverse transcription, integration and post-integration transcription. During the process of reverse transcription these unique regions are duplicated, forming two identical structures that are known as long terminal repeats (LTR), with a structure U3-R-U5 (Fig. 4). In the stage of provirus synthesis (when the lentiviral genome is double-stranded DNA) LTRs flank the genome at both ends. The 5' end of the R region in the 5' LTR is where transcription begins (+1 transcription). The U3 region of the 5' LTR is extremely important because it effectively controls transcription. In this region there are two main areas: a promoter area and an

Fig. 3 Proviral genomic structure of most common animal lentiviruses, showing genes *gag*, *pol*, and *env* and accessory genes. Several accessory genes are encoded in non-consecutive sequences and are expressed following splicing of the RNA.

enhancer area. The promoter area is closer to the beginning of transcription, and exhibits a TATA box 20–50 nt upstream of the cap site, +1 of transcription. The TATA box is present in the promoter region of many eukaryotic genes. Some lentiviruses also have a CCAAT box, another promoter sequence. The enhancer region is further upstream from the beginning of transcription and contains numerous sequences that are recognized by cell signaling factors. Upon activation of these enhancers, the promoter area triggers the beginning of the synthesis of RNA and DNA (Fig. 4). These sequences which bind cell signaling factors are collectively known as transcription factor binding sites or TBS, and include AP-1, AP-4, ATF, and many others. In some cases there is a TBS for NF- κ B or for LBP-1. In different lentiviruses, a variety of other sites exist, these include a gamma-activated site or GAS (FIV, HIV and CAEV), an interferon stimulated response element (ISRE, in FIV or HIV), interferon response factor-1 (IRF-1, CAEV), and hormone response element (HRE, FIV and HIV). The significance of these TBS is that viruses are silent in non-activated cells, but upon activation, the signaling process culminates in the entrance of molecules to the nucleus that can stimulate lentiviral replication and production of viruses. The other two regions of the 5' LTR, R and U5, play a primary role during the reverse transcription process. The LTRs have different sizes depending on the lentiviral species, ranging from about 311 nt (PLV) to 855 nt (HIV-2).

The region between the 5' LTR and the beginning of *gag* is defined as a non-coding region. It contains the primer binding site (PBS, 18 nt long complementary to the tRNA that functions as primer in the reverse transcription process), the packaging signal (ψ), and the leader region (L), which precedes the first coding sequence. This non-coding region serves as a donor for splicing processes that give rise to different subgenomic mRNAs. All retroviruses contain a sequence rich in purine, or polypurine tract (PPT) immediately before the U3 region of the 3' end. The PPT contains the site for initiating the positive strand of the viral DNA synthesis.

Encoded Proteins

Proteins encoded by essential genes are similar in all lentiviruses. External or surface proteins are usually glycosylated (at least SU), while inner proteins usually are not. Both external and inner proteins are very immunogenic, but the antibodies formed are not

Fig. 4 Schematic representation of viral RNA, proviral DNA and LTRs. The viral RNA contains identical R sequences at both ends, and a unique U5 in the 5' end, and U3 in the 3' end. This U5 and U3 become duplicated during the reverse transcription to give the LTRs, formed by identical U3-R-U5 at both ends. This viral DNA, known as provirus, integrates in the cell genome. There, it remains silent till cell signals cross the nuclear membrane and react with specific sequences in the U3 of the 5' LTR known as transcription factor binding sites or TBS (some of them are shown). This activates the promoter region of the LTR, leading to transcription from the 5' end of R or cap site.

able to eliminate the infection. The inner proteins are relatively conserved and can exhibit cross-reactions between different lentiviruses. They are named according to their weight (**Table 2**). Mature proteins are cleaved from polyprotein precursors. Accessory proteins and their functions are listed in **Table 3**.

Replication Cycle

The replication of retroviruses took time to be elucidated in part because the concept that RNA could be transcribed into DNA went against the accepted dogma that genetic information flows from the DNA to RNA, and from there to proteins. Unlike other retroviruses, which replicate in dividing cells, lentiviruses are preferentially expressed in differentiated cells. Some receptors and co-receptors have been identified, but many other receptors have not been identified yet. For example, despite the similar pathogenesis of HIV and FIV, unlike HIV the latter does not employ CD4 as a receptor, but CD134, a member of the family of receptors for TNF- α and nerve growth factors. In the case of SRLV it is likely that mannosylated residues in the Env protein are sensed by the mannose receptor (CD206), a C-type lectin endocytic receptor expressed on macrophages and dendritic cells. While the receptors for BIV or JDV have not yet been identified, there is evidence that BIV may use the C-C chemokine receptor 5 (CCR5), the main co-receptor used by the majority of strains of HIV-1 for infection of cells.

After the recognition between SU protein and its receptor, there are conformational changes that motivate the exposure of a hidden domain that in the case of HIV allows interaction with the co-receptors, CCR5 or CXCR4. This causes further changes that expose the fusion domain of TM, with the resulting fusion of the virus envelope with the cell membrane or of the endosome, allowing the entry of the viral particle (**Fig. 5**). Another entry mechanism can be in cells with receptors for the Fc domain of immunoglobulins (FcR) that trap antibody-coated particles (e.g., VMV). The penetration process concludes with the release of the core into the cytoplasm. The host cell has mechanisms to prevent this process, including TRIM5 α , which the virus has to circumvent. Once in the cytoplasm, the RT, likely in the context of a partially disrupted capsid, begins to transcribe the retroviral genome. First, thanks to the RNA dependent DNA polymerase activity (RdDp), it transcribes a single-stranded (minus sense) DNA molecule. As the RNA-DNA hybrid moves through the RT its RNase H activity degrades almost simultaneously the original viral RNA which served as template and through the DNA dependent DNA polymerase (DdDp) activity, an additional molecule of RT transcribes the complementary strand of nascent DNA, synthesizing a molecule of double-stranded DNA. In a complex process that involves duplication of regions from the 5' and 3' ends of the viral genome, LTRs that flank the provirus (DNA retroviral genome) are generated. Vif and Nef are important at this early stage, a reason for being present in the viral particle. Nef increases the effectiveness of RT, so that larger amounts of reverse transcribed DNA are produced, and Vif blocks the cell cytidine deaminase APOBEC3 that would increase the rate of error of the RT.

	Gag	Precursor of the structural proteins of the virus	Pr55	Pr50	Pr53	Pr55	
	MA	Matrix. Inner membrane layer. Confers rigidity and stability to the virion. Myristilated	p17	p15	p16	p16	p15
	CA	Capsid. Encapsulates the nucleocapsids. Intervenes in packaging. Synthesized in large quantities and its detection is used for diagnosis in some lentiviral infections	p24	p24	p26	p25	p26
	NC P6	Nucleocapsid. Surrounds and protects RNA Protein for viral encapsidation and budding of assembled particle	p7 p6	p10 -	p7 -	p14 -	p11 p9
<i>pol</i>	PR	Protease: Proteolytic cleavage of Gag and Gag-Pol to produce structural proteins and mature virion	p12	p14		p10	
	RT	Reverse transcriptase. Triple function: RNA dependent DNA polymerase (RdDp), DNA dependent DNA polymerase (DdDp) and RNase H to give the end result of double-stranded DNA from single-stranded RNA	p66/p51	p65		p68	
	dUTPase IN	Integrase. Integration of proviral DNA in the host genome	- p32	p14 p31	-	p14 p35	yes
<i>env</i>	PrEnv	Precursor of the viral envelope proteins	gp160		gpp145	pr185	
	SU	Surface protein on the viral envelope located in the outside of the virion. Interaction with receptors. Main domain for receptor binding. Attachment of virus to target cell. Determinant of tropism. Immunogenic, stimulates the synthesis of specific antibodies. It interacts with the extracellular domain of the TM. Always glycosylated	gp120	gp95	gp100	gp135	gp90
	TM	Transmembrane protein. With a cytoplasmic domain and a hydrophobic domain within the cell membrane. The interaction of TM with the lipid bilayer allows the anchoring of the SU-TM complex to the viral envelope. Mediates fusion between viral envelope and cell membrane. Induces syncytia. Immunosuppressant. Frequently glycosylated	gp41	gp40	gp45	gp46	gp4

Table 3 Regulatory and accessory genes, proteins encoded, their function and viruses in which they are present. CD4, molecule on surface of T-helper cells. MHC-I, major histocompatibility complex type I. Full names of the viruses are shown in [Table 1](#)

Gene	Protein	Function	Virus
<i>tat</i>	Tat	Potent transactivator that may greatly stimulate viral expression. Phosphoprotein located in the nucleus and nucleolus of the infected cells. Elongation of mRNA and transcription	BIV, CAEV, EIAV, HIV-1, HIV-2, JDV, SIV, VMV
<i>rev</i>	Rev	Regulates transport, processing and translation of viral mRNAs. Phosphoprotein located in the nucleus and nucleolus of infected cells.	BIV, CAEV, EIAV, HIV-1, HIV-2, JDV, VMV
<i>nef</i>	Nef	Endocytosis of CD4 and MHC-I at the cell membrane. Increase in the efficacy of RT, generating higher amounts of retrotranscribed DNA. Increase in the viral infectivity. Cell activation. Induction of apoptosis. Downregulation of E2 ubiquitin conjugating enzyme	HIV-1, HIV-2, SIV
<i>vif</i>	Vif	Enhancement of viral infectivity. Stabilization of the pre-integration complex. Blockage of the cell restriction APOBEC3G (cytidine deaminase) which increases the error rate of RT	BIV, CAEV, FIV, HIV-1, HIV-2, JDV, SIV, VMV
<i>vpr</i>	Vpr	Arrest of the cell cycle at G2. Transport of the pre-integration complex to the cell nucleus	HIV-1, HIV-2, SIV
<i>vpu</i>	Vpu	Enhancement of virion release. Degradation of CD4 and MHC-I	HIV-1
<i>vpv</i>			HIV-2, SIV
<i>vpw</i>			BIV
<i>vpy</i>			BIV
<i>tmx</i>	Tmx	Similar function to Nef	BIV, JDV
<i>orfA</i>		Similar functions to Tat, Vpu, Vpr and Nef. Arrest of the cell cycle at G2. Downregulation of E2 ubiquitin conjugating enzymes	FIV
<i>Jdvdp5</i>		Unknown	BIV
<i>S2</i>		Similar function to Nef	EIAV

Fig. 5 Schematic representation of the replication cycle of lentiviruses. Reverse transcriptase (RT) is shown in the shape of a star.

Proviral DNA, in the form of a pre-integration complex (PIC), crosses the nuclear membrane and, using the viral enzyme integrase present in the PIC, it is integrated into a host cell's chromosome. Vpr (also present in the virus particle) plays an important role in this process, directing the nuclear localization of the pre-integration complex and interfering with the cell cycle, stopping it in the G2 phase to facilitate integrase-mediated integration of the proviral DNA into the cell genome.

Once integrated, proviral DNA behaves as a Mendelian gene: when the cell divides, the progeny cells will contain the provirus. For this reason, lentiviral infections are lifelong, especially taking into account the cells that they infect, most of them indispensable for the immune response. Although integration is random, HIV-1 prefers to integrate within genes, while other retroviruses prefer exons or non-coding sequences. Integration appears to be a prerequisite for the infectivity, and although there is extra-chromosomal proviral DNA, it is not expressed. The integrated provirus can remain without being expressed for months or years, until the appropriate signaling molecules cross the nuclear membrane. They recognize specific short sequences of the U3 region of the 5' LTR, the TBS mentioned above, triggering the transcription of the lentiviral genome by the cellular RNA polymerase II, as if it were a common cellular gene. Therefore, lentiviruses are not expressed in resting cells and have to wait till these are activated, remaining latent till this occurs. This allows them to wait for adequate conditions to continue their replication cycle.

Integrated DNA serves as a template for the cellular RNA polymerase II to transcribe both spliced subgenomic mRNA, which will be translated to the characteristic polyproteins, and full-length viral RNA, which will be packaged into the viral particle. Accessory genes are expressed first, especially *tat*, *rev*, and *nef*. When the products of these genes reach appropriate levels, Rev facilitates the export of unspliced and partially spliced transcripts to the cytoplasm and translated in the form of polyproteins.

Of the proteins encoded by *env*, at least SU (and usually also TM) undergoes N-linked glycosylation. Both SU and TM are inserted into discrete microdomains in the plasma membrane related to lipid rafts. The internal proteins of the virus undergo limited modification (fatty acylation at N-terminus of MA) and accumulate at the plasma membrane and associate with the proteins SU and TM, in order to initiate the process of budding and assembly. Once concluded, the immature particles are released by budding. The PR cleaves the polyproteins inside the virions, giving rise to the mature virus particles. During these final stages, proteins such as cell MHC-I or CD4 are redirected to the degradation route, so they are not expressed on the cell surface, where they could interfere with virus release.

Reverse Transcription

The process of retrotranscription copies the information of the viral genome, contained in the molecule of single-stranded RNA, into a molecule of double-stranded DNA. During this process, the RT performs three enzymatic functions: DNA-dependent RNA-polymerase (RdDp), Ribonuclease H (RNase H), and DNA-dependent DNA-polymerase (DdDp). The RT activity lacks exonuclease activity (repairing) and, in addition, it has a high frequency of error when incorporating nucleotides, which makes that the final error rate of the RT ranges between 3×10^{-3} and 3×10^{-5} , depending on the retrovirus. The error rate of RT is higher with RNA templates than with DNA templates and varies according to the context of the reading. A characteristic of the activity of the RT is that throughout the process it switches from one strand of nucleic acid to the other, and may make mistakes at this time, allowing recombination.

Reverse transcription begins with the hybridization of the tRNA, which acts as the primer, with the PBS close to the 5' end of the viral genome (Fig. 6). From here, it extends the strand in the direction 5' until it reaches the end of R. RNA that forms part of the newly formed RNA-DNA hybrid is digested by the RNase H activity of the RT. The 3' end of the newly synthesized DNA and, now as a single strand, hybridizes with the R region of the 3' end of the viral RNA. This process is called the first strand transfer. RdDp

Fig. 6 Process of reverse transcription. The segments delimited by an orange outline represent RNA.

activity continues to extend the DNA molecule all the way towards the 5' end. RNase H activity degrades viral RNA 5' → 3', but is unable to degrade the polypurine tract (PPT) adjacent to the U3 region of the template RNA. This PPT functions as the primer to start DNA synthesis using DNA as template, in a 3' direction. This synthesis is extended by the primer, by copying a new PBS. RNase H activity removes the last vestiges of RNA, both in the area of PPT as in the primer. This creates two complementary PBS areas in each chain of DNA, allowing the second strand transfer to occur. As a new site is formed by where the DNA can be transcribed, RT, through its DdDp activity, synthesizes a strand of DNA complementary to the already synthesized. DNA synthesis continues until RT completes the complementary DNA, concluding the synthesis of the 5' LTR.

Biological Properties

Variability

Lentiviruses can achieve diversity both within individual hosts and within populations through spontaneous mutation rates ranging from 10^{-3} – 10^{-6} substitutions per site per year due to low polymerase fidelity and lack of proofreading capacity of RT. In addition to this remarkable mutation rate, lentiviruses can also create diversity by recombination, because RT needs to switch template from one strand of nucleic acid molecule to the other during the process of transcription (see above). These switches can match the nascent strand with non-corresponding sequences, causing recombination. This occurs in all lentiviruses, but the frequency of crossovers and factors promoting recombination can be variable. From the perspective of the lentivirus, variability has several advantages. Both mutations and recombination increase viral genetic diversity in fluctuating environments; the most

obvious implication of this is the development of escape mutants that allow the viral population to avoid the selective pressure applied by the host immune response or antivirals. Recombination is a mechanism to prevent the accumulation of deleterious mutations in the population, which would decrease its fitness. The extraordinary variability of some of the lentiviruses poses a major obstacle to vaccine development and drug usage. This, together with the persistent presence of lentiviruses in the infected cell, makes it very difficult to fight against these viruses.

Natural Hosts

As mentioned above, lentiviruses derive from a common ancestor that infected its host millions of years ago, and co-evolved with it as the progeny of this host diverged genetically. For this reason, related viruses may infect closely related species. Thus, it is possible that sheep are infected by CAEV and VMV by goats. It has also been shown that HIV-1 and HIV-2 come from SIV. SIV underwent several inter-species jumps; in the case of HIV-1, from chimpanzees and gorillas to humans, and in the case of HIV-2, from the sooty mangabey to humans. However, the mechanisms by which viruses from other animal species are able to infect a new one after these inter-species jumps remain unknown. In the case of FIV, although it usually is not passed between cat species due to the elusive and territorial nature of these animals, variants of the virus in different wild species have been isolated, including pumas, Asian leopard cats, ocelots, bobcats, jaguarundis, Pallas cats, cheetahs, leopards, lions, snow leopards and spotted hyenas. VMV can also infect wild ruminant species, such as moufflons. SIV infects a very high number of simian species, and it has been determined that up to 40 of the 69 species of African non-human primates act as natural hosts of SIV, including African green monkeys and mandrills.

Transmission

As other retroviruses, the lentiviral virions are sensitive to many physical and chemical agents including desiccation, temperature, acidic or basic pH values, etc. For these reasons they are usually transmitted in “short distances” by direct methods. Lentiviruses are usually exogenous viruses. This means that they are transmitted horizontally or in a contagious way, through cell-to-cell contact, as well as to the progeny of the infected cell. However, in the rare occasions in which a germ cell, a spermatozoid or an ovum, is infected, the provirus becomes integrated into the genome and is transmitted vertically from generation to generation of the animal, according to the patterns of Mendelian inheritance. These retroviruses that remain in the genome over millions of years are called endogenous retroviruses. Till recently, it was thought that lentiviruses had no capacity for germline integration. However, endogenous lentivirus-like viruses have been described recently in rabbits and lemurs, called RELIK and PSIV, respectively. This supports the concept that lentiviruses are more widespread than previously thought, can be incorporated into the host germline, and are ancient, existing prior to 12 million years ago. The phylogenetic relationships of RELIK (which is also found in hares) are shown in [Fig. 1](#).

For some lentiviruses, the most common horizontal transmission routes are the sexual route, the direct inoculation in tissues or bloodstream, through syringes with contaminated blood and bites (FIV and SIV), or during childbirth when the virus enters the body of the neonate through mucosal surfaces (HIV). In some cases lentiviruses can be transmitted by colostrum or milk, although not in SIV, possibly due to the low levels of CCR5 in the newborn. Some lentiviruses (i.e., BIV, HIV) can cross the placenta and infect in utero. EIAV is exceptional amongst not only lentiviruses but also retroviruses in that the transmission is performed by arthropod vectors (horseflies and deerflies). In JDV arthropods are also partly responsible for transmission.

Tropism

In many cases, target cells are those involved in the immune response. Some of the lentiviral species are lympho-tropic (infecting lymphocytes), others are macrophage-tropic (infecting cells of the monocyte/macrophage lineage, including in some cases, microglia, such as VMV, CAEV or EIAV), while others have a mixed tropism (infecting both lymphocytes and macrophages, such as SIV, HIV and FIV). Within the lympho-tropic species and strains, some infect T-helper cells ($CD4^+$), cytotoxic T-cells ($CD8^+$), $T\gamma\delta$ cells (common in cattle), null cells or B lymphocytes (e.g., BIV and JDV). Infected T-lymphocytes present an abnormal pattern of cytokine secretion, with increased expression of IFN and certain interleukins, such as IL-12 and IL-18. Some lentiviruses can also infect dendritic cells, which are key in immune responses. CAEV and VMV infect monocytes, but are not expressed until the cells mature to macrophages in the target organs.

Pathogenic Processes

Lentiviral infections usually follow a similar course, with an initial acute transitory stage, a latency stage in which the immune system is able to control the infection, and a final stage consisting of a new phase of fast replication, which determines the typical syndrome. However, many lentiviral infections pass unnoticed in animals because the virus does not produce any clinical sign. Asymptomatic infected animals can transmit the infection (carriers); the infection and the disease become apparent when the virus infects a different population. Typically, the acute stage, which develops 4–6 weeks after infection, is characterized by fever, lymphadenopathy, leukopenia (due frequently to neutropenia) and weight loss. This acute stage can last for a few weeks up to several months. This is followed by an asymptomatic stage, in which the animal appears to be healthy or with minimal clinical signs, which may last several years, during which the virus replicates at low rate, and the immune response is able to control it, but

producing a progressive impoverishment of the affected cell population. Finally, the immune response is unable to control the virus and the disease becomes apparent, with a significant increase of the viral load, an important deterioration of the immune system, immune deficiency with presence of respiratory, digestive, and possibly neurological clinical signs, as well as weight loss and hyperthermia, which lead to the death of the animal.

Immune Deficiency

Immune deficiency is one of the most common pathologies produced by lentiviruses. Several species include in their name this term, such as HIV-1, HIV-2, SIV, FIV and BIV, although in the latter the direct role of the virus in the clinical disease in infected cattle under natural conditions has not been shown clearly, and its true economic impact is hypothetical. Immune deficiency develops because many lentiviruses infect lymphocytes, especially T-cells. In the course of infection, CD4⁺ T-cells (T-helper cells) decrease, either by the direct action of the virus or due to the antiviral defense mechanisms. This decrease in CD4⁺ T-cells is exploited by opportunistic infections that become established and impair the clinical status of the animal, being responsible for its death in the majority of cases.

Immune deficiency is often accompanied by hematological abnormalities, mainly anemia, characteristic of FIV and EIAV infections. It is produced because viral surface glycoproteins coat red blood cells or erythrocytes, triggering complement-mediated destruction of these cells through a mechanism of type II hypersensitivity. Another consequence of immune deficiency is the development of tumors, which can be produced by an uncontrolled growth of cells (lymphoma).

Some of the alterations that appear as a consequence of immune deficiency are located on the skin and oral cavity (gingivitis), respiratory and gastro-intestinal tracts. Frequently the liver, kidneys and central nervous system are impaired.

Inflammation

VMV and CAEV produce mainly inflammation; processes associated with BIV and JDV also seem to be more related to inflammation than with immune deficiency. This could be due to the earlier sacrifice of cattle than of the other animal species mentioned in the paragraph of immune deficiency. The inflammation directly attributed to infection by CAEV or VMV is located in the mammary gland, joints, lungs or central nervous system (meningoencephalitis), prevailing one over the other depending on the infecting virus. As in the other lentiviruses, CAEV and VMV can remain latent for many months with little or no expression. The myriad of mechanisms that regulate viral replication and lead to increased viral loads and more serious outcomes of disease remain unclear. However, it is recognized that specific cell transcription factors activate viral gene expression when interacting with specific proviral DNA sequences included in the LTR, the transcription factor binding sites (TBS) mentioned above.

SRLV constant replication in tissue and the subsequent immune response produce chronic inflammation causing pathological changes observed in the target organs of animals infected by the virus. As a result, the multisystem inflammatory disease that characterizes SRLV infection has an immunopathogenic origin. The main change in the affected tissues is infiltration by mononuclear cells (lymphocytes, macrophages and plasma cells). Cells accumulate and organize in lymphoid follicles. The final phase of the pathogenesis begins when the clinical disease appears. Depending on the clinical form, the animal can die rapidly or remain chronically infected.

The inflammatory processes triggered by lentiviruses are associated with the production of cytokines, which can regulate viral transcription through the cellular signaling pathways mediated by the TBS in the proviral LTR as explained above. For example, cytokines IFN- γ and TNF- α , present in arthritic joints of animals infected by CAEV, have shown to activate viral transcription via recognition of the corresponding gamma activation site (GAS) and TNF activation site (TAS) present in the U3 of CAEV.

Cell Defenses and Viral Mechanisms to Evade Them

When attacked by viruses, cells display innate response mechanisms to avoid their productive infection. Some of the cellular mechanisms to fight against lentiviruses are TRIM5 α , APOBEC3 or tetherin. TRIM5 α induces a premature uncoating of the viral core, by recognizing the incoming viral capsid, inducing its proteasome-dependent degradation. This impairs integration and significantly reduces proviral load and viral production. APOBEC3 is a cytidine-deaminase that causes uracil accumulation in negative-strand nascent DNA, leading to detrimental G-to-A mutations in the proviral DNA. This molecule may be incorporated into progeny virions in producer cells (passenger APOBEC3) and inhibit lentiviral replication in the following replication cycle in target cells. Lastly, tetherin is able to trap virions on the surface of infected cells, preventing virus release, and therefore, virus transmission between cells. These mechanisms are very specific against particular lentiviruses, and this innate immune response is responsible for preserving the species barrier.

In response, lentiviruses have developed mechanisms to counteract these restriction factors. For example, the high genetic heterogeneity found within the capsid region is likely a way to escape TRIM5 α . In HIV, FIV, BIV, SRLV and EIAV infections, the viral protein Vif has the main function of avoiding APOBEC3 incorporation into viral particles, restricting the probability of incorporating wrong nucleotides. Vif also triggers the degradation of most APOBEC3 proteins. Vpu is particularly dedicated to bind tetherin and degrade it via proteasome. This so-called "evolutionary arms race" has led to the selection of somatic genes encoding virus-interacting proteins. So far, these innate mechanisms have been partially unveiled in the simian or human counterparts, and equine, ovine, bovine, and feline lentiviruses are being actively studied to decipher the important restriction mechanisms in these species.

Animal Lentiviral Infections

Feline Immunodeficiency and Puma Lentiviral Infections

Feline immunodeficiency virus was initially isolated from cats (*Felis catus*) in Petaluma (CA, USA) in 1986. As mentioned above, besides cats, other felids, such as cheetah, lions, leopards or hyenas may be infected by the virus. The most recent release of the ICTV (2018) recognizes two different viral species, highly related to FIV, identified in mountain lions (*Puma concolor*) and bobcats (*Lynx rufus*), which are known as puma lentivirus A (PLVA) and B (PLVB). However, the list of FIV-related lentiviruses in wild felids is increasing quickly. FIV is considered a good animal model for the study of HIV, as its biochemical and morphological properties are very similar, though antigenically they are distinct. Also, though both HIV and FIV infect CD4⁺ T-cells, the latter enters cells through CD134, a member of the TNF- α and growth factor receptors. CD134 is highly expressed in active lymphocytes, monocytes/macrophages and dendritic cells. FIV is mostly transmitted through direct inoculation of the virus through bites, the reason why it is most prevalent in adult male cats. After an initial period of 4–6 weeks with no signs, cats develop an acute phase with hyperthermia, lymphadenopathy, leukopenia (mostly neutropenia), and weight loss. This is followed by a long asymptomatic phase which may last many years. In fact, 12% of the healthy cat populations are considered to be unapparent carriers. Infected cats may die in old age of etiologies unrelated to FIV-infection. However, some develop clinical immune deficiency with increased viral loads due to the immune impairment, accompanied with respiratory and intestinal clinical signs, gingiva-stomatitis, hyperthermia, etc., which constitute the so called feline acquired immune deficiency syndrome or FAIDS. FIV, rather than opportunistic bacteria, may be directly responsible for the intestinal dysfunction, as it may cause blunting of the villi and dilation of the crypts. In contrast to FIV, lentiviruses of wild felids have not historically been associated with significant pathogenicity. However, several captive African lions have manifested clinical signs or hematologic abnormalities associated with lentiviral infection.

A commercial vaccine is available to prevent FIV infection in cats, but its use remains controversial, including whether or not the vaccine effectively induces cross-protective immunity against the various naturally circulating virus strains.

Bovine Immunodeficiency (BI) and Jembrana Disease (JD)

BIV was first isolated in 1969 in the USA from a progressively deteriorating 8-year old pregnant Holstein dairy cow (*Bos taurus*), identified as R-29, with wasting syndrome, lymphadenopathy, leukocytosis, lymphocytosis, fatigue, diminished milk yield and neurologic disorders. Serology has shown that BIV is present worldwide; however, the direct role of BIV in clinical disease among cattle infected under natural conditions is not clearly demonstrated and the true economic impact of BIV-infection remains conjectural. However, an acute disease in Bali cattle (*Bos javanicus*), Jembrana disease, endemic to parts of Indonesia, was described in the 1990s and is thought to have arisen from BIV via an unknown transmission event. The clinical signs observed in BIV-infection are more related to the inflammatory events characteristic of VM or CAE (see below) than immune deficiency itself. BIV targets monocytes and macrophages, inducing some immune dysfunction such as decreased superoxide anion production, phagocytic activity and chemotaxis. On the other hand, JDV has a high morbidity and mortality of up to 20%. JD is characterized by an acute stage 5–12 days post infection, with fever, lymphadenomegaly, lethargy, anorexia, panleukopenia, splenomegaly, hemorrhages and very high viral loads. There is no recurrence of disease in recovered animals but viral loads remain high during at least 2 years. JDV is often described as an atypical lentivirus, because of the low level of viral variation in vivo, the delayed antibody response, and the ensuing immunological control which prevents subsequent heterologous infection. There is an inactivated tissue-derived vaccine against JDV to control the disease in Indonesia.

Visna-maedi (VM) and Caprine Arthritis and Encephalitis (CAE)

VM was first described in Iceland in the 1930s. VMV was isolated from cases of interstitial pneumonitis (*maedi* = shortness of breath in Icelandic) and demyelinating leukoencephalomyelitis (*visna* = wasting in Icelandic). CAEV was first isolated in 1980. They are collectively called Small Ruminant Lentiviruses (SRLV). Transmission is related to body fluids, mainly respiratory exudates and milk or colostrum. Both VM and CAE are prevalent worldwide, although the prevalence is much higher in developed countries, which seems to be related to the custom of feeding lambs or kids with milk pooled from all the mothers, which favors transmission, and to the intensive rearing system. Both viruses can infect sheep and goats and cross-infections have been observed both experimentally and naturally. Nevertheless, the infection by VMV is more frequent in sheep and the infection by CAEV in goats. SRLV have in vivo tropism for monocytes, macrophages and dendritic cells, but may also infect cells of the central nervous system and others. As with other lentiviral infections, there is an initial short phase of viremia. Infected monocytes and macrophages spread the infection. The replication in monocytes and macrophages does not take place until these cells mature in the target organs. The infection remains latent for a period of time which depends on the viral strain and mainly on the individual susceptibility, and the animal can die in a short time or remain chronically infected. The continual replication of SRLV in tissues and the ensuing immune response causes a chronic inflammation that originates the pathological changes observed in target organs of SRLV-infected animals. Consequently, as in other lentiviral infections, the multisystem inflammatory disease that characterizes SRLV infections is immune-pathogenic in nature. The final stage of the pathogenesis begins when the clinical disease starts. Clinical forms of both VM and CAE are respiratory, nervous, mammary and joint disease. Although normally the process is

subclinical, a small percentage of the animals can display one or more of these forms or even all four of them. Sheep usually develop respiratory and mammary clinical signs, while goats display nervous and joint forms.

Equine Infectious Anemia (EIA)

EIA is considered a worldwide disease that occurs only in members of the family Equidae. It was first identified as an infectious disease of horses by veterinarians in France in 1843, and shown to be produced by a filterable agent in 1904. The disease is different from other retroviral diseases in that it is transmitted mostly by insect vectors (especially horseflies and deerflies), but also by hypodermic needles and other veterinary instruments. Sexual transmission of EIAV has not been demonstrated to date. The cell target during persistent EIAV infections appears to be exclusively cells of the monocyte/macrophage lineage, especially macrophages resident in tissues, such as liver, kidney, spleen. Viremia observed during episodes of chronic EIA result primarily from the production and release of EIAV from infected tissue macrophages, rather than an extensive infection of blood monocytes.

Field isolates and laboratory strains of EIAV differ markedly in their pathogenicity; processes can be asymptomatic to lethal. Characteristically, the course of the infection is initially acute (first month), followed by chronic disease (first year) to progress into an asymptomatic lifelong stage thereafter. Horses suffer acute and chronic disease, while donkeys and mules typically experience asymptomatic infections. Acute disease is often associated with the first exposure to the virus, with fever, thrombocytopenia and hemorrhages evident from 7 to 30 days after exposure, though anemia or edema is not seen at this point. After this first stage, horses become clinically healthy but recurring episodes of the disease appear at irregular intervals, ranging from weeks to several months. Stress or immunosuppression trigger these viremia and reactivation episodes. Typically, horses will develop weight loss, anemia, diarrhea, and edema. Most of these signs are thought to be the combined effect of immune-mediated lysis of virus-infected cells and an immune complex-mediated inflammatory response. During the first year after infection, clinical episodes in horses with chronic EIA are more severe and frequent, and they usually disappear thereafter, and the horse becomes a lifelong inapparent carrier.

Currently there is no effective vaccine for the prevention of EIAV infection and disease, mostly due to the large antigenic diversity of the virus.

Animal Morbilliviruses (*Paramyxoviridae*)

Carina Conceicao and Dalan Bailey, The Pirbright Institute, Pirbright, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Classification

The Morbillivirus genus belongs to the *Paramyxoviridae* family in the order *Mononegavirales*. Within the genus there are now seven recognized species (summarised in Table 1). For the purpose of clarity and concordance with the published literature, we will refer to individual viruses using their commonly used abbreviations (Table 1). The morbilliviruses are genetically closely related, with the most distant, formally classified, virus being feline morbillivirus (FmoPV) (Table 1 and Fig. 1). At the genomic level nucleotide identities vary between 53% (FmoPV and measles virus, MeV) and 76% (canine distemper virus, CDV and phocine distemper virus, PDV). Current theories on the evolution of morbilliviruses are summarised excellently in Nambulli *et al.* (2016) (see "Further Reading"). Of particular interest, rinderpest virus, RPV (or its ancestor) is thought to have emerged following the domestication of cattle. This ancestral virus is also thought to be the source of MeV, following zoonotic transmission to humans. It is well known that MeV spread to the North and South Americas in the 1500s causing devastating epidemics in indigenous populations; however, it is less widely appreciated that CDV is thought to have originated in the Americas, and then spread to Europe following colonisation. PDV may in turn have originated from spillover of CDV into aquatic mammals, perhaps as recently as the twentieth century. The recent identification of a wealth of morbillivirus sequences in bats and rodents now indicates that the established morbilliviruses may have actually emerged from related small mammal viruses. The close molecular relationship of morbilliviruses is also evident in their related antigenicity, with various viruses being able to provide cross-protective immunity.

Virion Structure

Pleomorphism is a feature of morbilliviruses, which translates to the production of particles ranging from 150 to 500 nm in diameter. These viruses are surrounded by a lipid bilayer derived from the host cell decorated with the viral glycoproteins haemagglutinin (H) and fusion protein (F), which can be seen as extruding spikes on the surface of morbillivirus virions (Fig. 2(A)). Inside the viral envelope, the matrix protein M forms a highly ordered lattice that interacts with the lipid bilayer, supporting the virion and packaging the viral genome within. The morbillivirus genome consists of a non-segmented, single-stranded, negative sense RNA molecule encapsidated by the nucleoprotein N in a helical nucleocapsid (Fig. 2(A)). The RNA-dependent RNA polymerase (RdRp) termed the large (L) protein and its co-factor, the phosphoprotein (P), associate with the N-RNA complex, forming the ribonucleoprotein complex (RNP). These RNP complexes assemble into a helical

Table 1 Host range, epidemiology and phylogeny of morbillivirus species identified to date

Species (2018-onwards)	Former species name (pre 2018)	Common abbreviation (For isolates)	Typical host	Sub-species classification	Geographic location	Genome length; % identity to MeV	Example sequence accession number
Canine morbillivirus	Canine distemper virus	CDV	Domestic dogs/ Carnivores	10 lineages (see Section Epidemiology and Host Range)	Global	15,690 nt; 61%	NC_001921.1
Cetacean morbillivirus		CMV	Cetaceans (whales, dolphins)	Previously defined as two species: Porpoise and dolphin morbilliviruses	Uncharacterised (likely global)	15,702 nt; 64%	NC_005283.1
Feline morbillivirus		FmoPV/ FeMV	Domestic cats	Not defined to date	Uncharacterised (likely global)	16,050 nt; 53%	JQ411014.1
Measles morbillivirus	Measles virus	MeV/MV	Humans	19 genotypes identified to date, only 6 currently circulating ^a	Global	15,894 nt	NC_001498.1
Phocine morbillivirus	Phocine distemper virus	PDV	Pinnipeds (seals)	Not defined to date ^b	Uncharacterised (likely global)	15,696 nt; 60%	NC_028249.1
Rinderpest morbillivirus	Rinderpest virus	RPV	Cattle	Lineages 1–3 (see Section Epidemiology and Host Range)	Extinct	15,882 nt; 69%	NC_006296.2
Small ruminant morbillivirus	Peste-des-petits-ruminants virus	PPRV	Sheep and goats	Lineages 1–4 (see Section Epidemiology and Host Range)	Northern and sub-Saharan Africa, Middle East, Asia	15,948 nt; 65%	NC_006383.2

^aCirculating genotypes are B3, D4, D8, D9, G3 and H1 (CDC, <https://www.cdc.gov/measles/lab-tools/genetic-analysis.html>).

^bThe 1998 and 2002 outbreaks may form two distinct lineages.

Fig. 1 Genetic diversity and ecology of the morbilliviruses. Rooted phylogenetic tree of the morbilliviruses, constructed using a neighbour-joining algorithm from full-length H sequences with at least 4 representative sequences of each species. Each branch corresponds to the diversity found within the sequences analysed with the genetic distance between branches indicated (0.2). The host silhouettes indicate the naturally infected hosts where disease has been recorded.

Fig. 2 Virion structure and genome composition of the morbilliviruses. (A) Schematic representation of morbillivirus virions illustrating the virally-encoded glycoproteins embedded in the host-derived envelope. Inside the M protein supports the viral envelope and interacts with the ribonucleoprotein complex (RNP), composed of the RNA genome encapsidated by the N protein, the viral polymerase L and its co-factor, the P protein. (B) Morbillivirus genomes strictly adhere to the “rule of six”, with one monomer of N protein encapsidating 6 nucleotides (nt) of RNA. (C) The morbillivirus genome comprises six genes that encode for six structural proteins (3′ - N, P, M, F, H and L - 5′) as well as two non-structural proteins V and C, expressed from the P gene, by gene editing and through use of an alternative open reading frame (ORF), respectively. The ORFs and intergenic regions are drawn to scale. (D) The RNA genome of morbilliviruses is composed of seven cis-acting elements that define the gene start (GS), IG and gene end (GE) for each of the six genes. At the 3′ and 5′ ends are conserved and complementary sequences that constitute the genome promoter (GP) for the production of viral mRNA and the antigenome promoter (AGP) for the production of full-length RNA genome, respectively.

configuration forming a characteristic herringbone-like structure, visible by electron microscopy. The RNP is the minimum required unit to initiate transcription and replication of viral RNA *in vitro*. Infectious morbillivirus virions possess at least one RNP; however, it has been shown for MeV that more than one RNP can be incorporated without affecting viral fitness.

Genome

Morbillivirus show variable genome lengths ranging from 15.5 to just over 16 kb (Table 1). Genome length conforms to the ‘rule of six’, since each N monomer encapsidates six nucleotides of RNA. The rule of six ensures the whole viral genome is encapsidated by the nucleoprotein, as this would otherwise negatively affect transcription and replication activity by the RdRp (Fig. 2(B)). Interestingly, PPRV was shown to not strictly conform to this ‘rule of six’ as two nucleotide insertions, or one nucleotide deletion at the 5′ end of a minigenome, did not severely affect the RdRp activity. However, the hexameric genome length of morbillivirus is prominently evident in nature, as demonstrated by a novel variant of PPRV that possessed a 6-nucleotide insertion in its genome,

when compared with other strains of PRRV. All morbillivirus genomes are composed of six genes (3' *N, P, M, F, H* and *L* 5') which encode for eight proteins (**Fig. 2(C)**). The two non-structural proteins C and V are encoded within the P open reading frame (ORF), by alternative translation initiation and RNA editing, respectively. All genes are separated by untranslated regions (UTRs), which contain in the following order, gene-stop signals (including polyadenylation signals) at the end of the upstream gene, a non-transcribed trinucleotide-intergenic region (IG) and lastly, gene-start signals for the expression of downstream genes (**Fig. 2(D)**). In morbilliviruses the IG is always 3 nt; however, the whole UTR region between genes can be up to 200 nucleotides in length, except for the UTR between the M and F ORFs, which can be over 1000 nucleotides. This long UTR is unique to morbilliviruses and is thought to play a role in mRNA translation, glycoprotein expression and virulence, as reduction in its size resulted in CDV attenuation *in vivo*. There are also conserved and complementary sequences at the 3' and 5' end of the genome, used as promoters by the RdRp (**Fig. 2(D)**). Preceding the N ORF at the 3' end is a conserved 52-nucleotide long leader sequence, followed by an IG and the 3' UTR of the *N* gene. This 109-nucleotide long region constitutes the genome promoter (GP) that directs the production of viral messenger RNA (mRNA) or full-length antigenome (positive sense RNA), which subsequently serves as the template for the production of nascent full-length genomic RNA (negative sense). Similarly, at the 5' end of the genome there is a conserved 37-nucleotides long trailer sequence that together with the 5' UTR of the *L* gene comprises the antigenome promoter (AGP), which directs production of full-length genomic RNA from the antigenome. Of note, the recently identified FmoPV possesses a 400-nucleotide long trailer sequence, giving it the largest morbillivirus genome identified to date (16,050 nucleotides). Although relatively well conserved, these GP and AGP sequences are thought to be species-specific; however, weak interactions can occur between the RNP of one virus and the GP and AGP of another, as was shown for RPV and PPRV using surrogate minigenome reporter assays. Even minor changes in sequence can have significant consequences on viral replication *in vivo*, e.g., exchanging the GP and AGP between a vaccine and virulent strain of RPV significantly altered pathogenesis in infected cattle.

Proteins

The nucleoprotein is the most abundant structural protein in morbillivirus particles, since significant amounts are required to encapsidate the full length RNA genome during the formation of the RNP. PPRV and RPV encode a 525-amino acid (aa) long protein whereas the N protein of CDV and aquatic morbilliviruses (cetacean morbillivirus, CeMV and PDV) is 523-aa long. All paramyxovirus N proteins can be divided into two main regions: the N_{core} located at the N-terminus and the N_{tail} located at the C-terminus. The N_{core} is a conserved structural domain containing the regions for self-assembly, RNA binding and P binding, while the disordered N_{tail} is involved in mediating RdRp activity *via* interactions with the N_{core} and the RdRp co-factor P. The importance of N_{tail} was illustrated by reports that truncated forms reduced the pathogenesis of recombinant CDV viruses *in vivo*. The predisposition of this protein to create nucleocapsid-like structures can also be observed when the protein is expressed in isolation in different systems. A closer look at these structures revealed that N_{core} is the main domain responsible for formation of nucleocapsid structures, as mutations impaired N-N assembly and RNA packaging.

The functional RNP complex is also composed of the phosphoprotein P, which both acts as a chaperone for the N protein by interacting with N_{core} to maintain solubility in the cytoplasm but also as cofactor for the RdRp L polymerase. While PPRV encodes a 509-aa long P protein, the respective RPV and PDV proteins are 507-aa long, with CeMV encoding the smallest P protein (506 aa). The P gene also encodes two other gene products: the non-structural proteins C and V. The C protein is 186-aa long and produced by leaky scanning from an alternative start codon downstream of the P protein ATG. By contrast, the non-structural V protein is produced by viral RdRp-mediated RNA editing. At a specific motif of three G residues within the P gene sequence a G residue is inserted during transcription, resulting in a subset of V viral mRNAs that share the same N-terminal sequence as P but have a frame-shifted C termini. The C protein has been shown to regulate transcription and replication of genomic RNA in RPV and inhibit type I interferon (IFN) responses in PPRV. Although the C protein is broadly thought to act as an IFN antagonist, Messling *et al.* suggested that this protein is mostly involved in viral spread within the host, while the V protein is the main functional effector of IFN inhibition. In fact, the V proteins of RPV, PPRV and CDV have all been shown to inhibit type I and type II IFN responses. Mechanistically, V protein blocks type II IFN responses through interactions with STAT1, preventing translocation to the nucleus and activation of interferon-stimulated genes (ISGs).

The M protein plays a pivotal role in viral structure and assembly of progeny virions, and is the minimum requirement for the release of virus-like particles (VLPs). During morbillivirus infection, the M protein associates with the RNP *via* interactions with the N-terminus of the N protein, not only mediating viral RNA encapsidation into progeny virions, but also particle synthesis. In addition, the matrix protein is involved in recruiting the glycoproteins to the inner surface of the cell membrane to enable virus budding. The majority of the M protein is found within the cytoplasm; however, it can also be found in the nucleus of infected cells, where for MeV it was reported to inhibit host transcriptional machinery.

The fusion protein F is one of two viral glycoproteins present on the surface of the virion, orchestrating virus-cell and cell-cell fusion during morbillivirus infection. F is produced as an inactive precursor F_0 , which is proteolytically cleaved and folded into the metastable prefusion state consisting of F_1 and F_2 subunits, linked by a disulfide bond. The F_1 subunit is known to contain an N-terminal hydrophobic fusion peptide, two heptad regions (HR1 at the N-terminus and HR2 at the C-terminus), a transmembrane domain and a C-terminal cytoplasmic tail. A third heptad repeat termed HR3 is located in the F_2 subunit. Together, these heptad regions mediate membrane fusion upon F triggering *via* conformational changes that enable the fusion peptide (located in HR1) to dock with the target membrane. For the functionally trimeric F protein to be activated and promote virus-cell membrane

fusion, the viral particle first needs to bind its cellular receptor, an interaction mediated by the viral attachment protein H. The tetrameric H protein interacts with the F trimer primarily through an extended stalk domain. Each H monomer is composed of an N-terminal cytoplasmic tail, a transmembrane domain, stalk and a β -propeller with six β -sheets arranged as a globular head at the C-terminus. Structural studies of the H protein bound to its cellular receptors have revealed that $\beta 4$, $\beta 5$ and $\beta 6$ constitute the receptor binding domain (RBD). The H protein is the main target of the host's humoral immune response and many of neutralizing antibodies (nAbs) raised upon morbillivirus infection recognize the RBD, presumably serving to block attachment. Since this protein binds to two distinct cellular receptors, the ability to alter of the RBD sequence to drift away from nAb recognition is limited, which may explain the mono-serotypic nature of morbillivirus.

Lastly, the largest protein encoded within the morbillivirus genome is the RdRp polymerase. This protein is responsible for transcription of genomic RNA into mRNA as well as replication of nascent full length RNA genomes *via* a full length positive-sense intermediate, the antigenome. Since the entire morbillivirus replication cycle occurs in the cytoplasm of the cell, the L protein also carries out capping, methylation and polyadenylation of nascent viral mRNAs to allow efficient translation by the host cell machinery.

Life Cycle

Morbillivirus infection begins with the attachment of virions to the surface of the host cell *via* a proteinaceous cellular receptor. CD46 was the first receptor identified, however it was later shown that this is only recognized by laboratory-adapted MeV strains and not by wild type (WT) strains. Later, the signalling lymphocyte activation molecule (SLAMF1) was identified as the immune cell receptor for both WT and vaccine strains. This receptor is mainly expressed on activated B and T cells, macrophages and dendritic cells. In addition to being lymphotropic, morbilliviruses are also epitheliotropic; with the cellular adhesion molecule Nectin-4 being the receptor on epithelial cells. Experiments for many of the established morbilliviruses indicate that SLAMF1 and Nectin-4 are universal morbillivirus receptors. Genome entry occurs following F protein-mediated fusion of viral and cellular membranes; however, recently it was shown that SLAMF1 can also mediate endocytosis of the virions in a macropinocytosis-like manner.

The H and F proteins exist as a hetero-oligomeric complex on the surface of the virion. Binding of H to its cellular receptor brings the viral and cellular membranes into close proximity to enable fusion. To date, five models of morbillivirus fusion triggering have been described. The generally accepted model, summarised in Fig. 3, is that morbillivirus fusion is triggered following receptor attachment by H, which results in conformational changes in the head domain of the H protein and partial unfolding of the central stalk region. Unfolding of this region, which is known to interact with F, causes dissociation of the highly energetic and unstable prefusion form of this trimer. Receptor binding by H lowers the energy barrier required for F triggering and this, coupled with the release of the prefusion form, enables the protein to undergo a series of irreversible conformational changes until it stabilizes in its post-fusion state. This includes structural rearrangement of the heptad regions, resulting in docking of the fusion peptide in the target membrane and 'pulling' of the viral and cellular membranes into close proximity. Although fusion with the cellular membrane typically occurs at neutral pH, this is a highly energetic process, thus more than one F trimer might be triggered to overcome this energy barrier, as seen with other paramyxovirus. Finally, an F-mediated membrane pore is formed between the viral and cellular membranes, which expands in an actin cytoskeleton-dependent manner to enable the release of the viral RNP into the cytoplasm of the host cell.

Following F and H-mediated entry, the RNP is released into the cytoplasm of the host cell. Here, the incoming RdRp initiates the process of transcription by first binding to the GP sequence at the 3' end of the genomic RNA. For morbilliviruses, transcription continues *via* a 'stop-start' mechanism, with the RdRp only moving to the next gene once the mRNA from the previous gene has been synthesized and released. Importantly, during this gene-transition process at the IG the RdRp may fall from the genomic

Fig. 3 Step-wise model for membrane fusion in the morbilliviruses. The H protein binds to the SLAM receptor (1), resulting in conformational changes in H (2). These changes promote detachment of the H and F proteins and activation of the latter, triggering structural changes in F (3). The heptad repeats of F form a three-helix bundle wherein the fusion peptide docks with the plasma membrane (4), pulling the two membranes into close proximity and promoting merging of the viral and cellular membranes (5). Lastly, F in its stable post-fusion state enables pore formation and expansion with consequent release of the RNP into the cytoplasm (6).

Fig. 4 Transcription and replication of the morbillivirus RNA genome. The RNA genome is transcribed by the viral RdRp, which can only commence transcriptional activity at the 3' end of this molecule. Following transcription of each gene, beginning with *N*, the RdRp either falls off the template at the intergenic region or continues transcription of the next gene, *e.g.*, *P*. This results in a transcriptional gradient whereby the genes closest to the GP are transcribed to higher levels than the promoter distal genes, *i.e.*, *L* is transcribed with the least frequency. The RdRp also carries out genome replication from the antigenome promoter (AGP at the 5' end of the genome), a process which occurs following the production of an encapsidated, full-length intermediate called the antigenome. This serves as the template for production of full-length, N-encapsidated RNA genomes which can be incorporated into progeny virions.

template. Since re-attachment of the polymerase and further transcription can only commence from the 3' GP, a transcriptional gradient results, whereby the genes closest to the GP are transcribed at higher levels than promoter distal genes (Fig. 4). This gene expression strategy reflects the relative requirement for individual proteins in viral replication, with the order of the genes being conserved in all morbilliviruses. Of note, the F and H glycoproteins are synthesized in the ribosomes of the rough endoplasmic reticulum and trafficked through the Golgi complex where post-translational modifications occur, including proteolytic cleavage of F₀ and glycosylation of both proteins.

The RdRp also carries out replication of nascent full-length RNA genomes, initially through production of a positive-sense intermediate; the antigenome, which is also N-encapsidated (Fig. 4). Once this positive-sense intermediate is produced, the RdRp binds to the AGP at the 3' end of the antigenome and synthesizes nascent, full-length, negative-sense RNA genomes, also N-encapsidated. The switch from transcription to replication is poorly understood; however, the most widely accepted model is that increasing levels of soluble N protein mediate the interchange from transcription to replication. Anderson *et al.* showed that deletion of the proximal region of the 3' UTR between the M and F ORFs of CDV influenced replication initiation but the exact mechanism for this remains poorly characterised. It has also been suggested that the presence of two variable-state RdRps, specific for replication or transcription, mediate this switch.

Finally, the synthesized viral components assemble at the plasma membrane to be incorporated into progeny virions that are released from the host cell. The exact mechanism by which morbilliviruses assemble and bud remains largely uncharacterized, therefore we will couple studies on other paramyxoviruses to address this step of the life cycle. It is widely accepted that the M protein plays a major role in assembly of the viral proteins and RNPs as well as budding of nascent virions. Budding of morbilliviruses from polarised epithelial cells occurs at the apical surface, requiring directional movement of the viral components to this surface. Apical budding is largely dependent on specific sorting of the glycoproteins, as otherwise these proteins accumulate at the basolateral membrane. This sorting is accomplished *via* interactions between the M protein and the cytoplasmic tails of the glycoproteins, as demonstrated for MeV, Sendai virus and para-influenza virus 5. Furthermore, budding at the apical surface also requires direct trafficking of the RNP complex to this site. Nakatsu *et al.* recently showed that apical budding of MeV in polarised epithelial cells is dependent on trafficking of the RNP complex to the cell membrane *via* the recycling endosome pathway (REP), employing Rab11A-positive vesicles. In contrast, budding from nonpolarized cells occurs in a REP-independent manner. Another cellular component required for efficient release of morbilliviruses is the actin cytoskeleton, as its specific disruption with pharmacological inhibitors severely impairs the trafficking of the M protein and RNPs to the surface of the cell. It has been suggested that once the viral proteins reach the cell surface they accumulate at lipid raft domains; CDV virions were reported to contain cholesterol while MeV RNPs and M proteins were shown to localize to lipid rafts. In contrast to viral assembly, particle budding requires actin cytoskeleton destabilization, allowing the mature bud to form. Bringolf *et al.* used a structure-guided mutagenesis approach to show that M protein oligomerization plays a key role in promoting virus budding, identifying that accumulation of M dimers at the cell surface induces membrane curvature and formation of the viral bud leading to virus egress, which Salditt *et al.* showed to be ESCRT-independent. Once the viral bud is formed, nascent virions 'pinch off' from the surface of the cell *via* a mechanism that remains largely uncharacterised. Lastly, it has been shown that morbilliviruses downregulate their cellular receptors on the surface of infected cells, a process which could facilitate release of cell-free virions. The life cycle of morbilliviruses is summarised in Fig. 5.

Fig. 5 Morbillivirus life cycle in the cell. A schematic overview of the morbillivirus replication cycle with viral proteins coloured, as in Fig. 2. (1) The virion attaches to the cell receptor through its H protein, which activates the F protein and triggers fusion of the viral and cellular membranes, with release of the RNP into the cytoplasm of the host cell; (2) the viral genome is transcribed, capped and polyadenylated by the RdRp to be translated by the host cell ribosomes (3); (4) Unlike the other viral proteins, the F and H proteins are translated by ribosomes in the rough endoplasmic reticulum and further processed in the Golgi complex; (5) At a later stage, the RdRp switches from genome transcription to genome replication to produce nascent viral RNA that will be incorporated into progeny virions; (6) The RNP as well as the M, F and H proteins are sorted to the surface of the cell membrane where nascent particles are generated by budding.

Epidemiology and Host Range

RPV

Historically recognized as significant diseases of humans and animals, RPV and MeV were properly described during the 16th and 17th centuries; however, the first evidence for rinderpest disease dates back to the 4th century AD. RPV is thought to have originated in Asia, followed by emergence in Europe in the 18th century, where the virus was described as the causative agent of cattle plague. By the end of the 19th century, RPV had reached the African continent, spreading to Australia and South America by the middle of the 20th century. Discovery of the virus, coupled with sequencing technologies, allowed RPV isolates to be classified into three lineages based on sequence variability (up to 11%) in the *F* gene. These lineages accurately represented the geographic distribution of RPV during the 20th century: lineage I included East, West and North African isolates, lineage II represented isolates from East and West African countries, while lineage III included Southern Asian isolates of RPV. The high prevalence of RPV across three continents and its enormous economic impact on agriculture, especially in twentieth century Africa, resulted in the implementation of a coordinated mass vaccination campaign to eradicate the disease. Following years of effort RPV was declared eradicated in 2011 (see below).

PPRV

In the middle of the 20th century, PPRV was identified as the causative agent of '*peste des petits ruminants*' (plague of small ruminants) in West Africa. Although initially thought to be a variant of RPV the origin of this genetically distinct virus remains uncertain. In fact PPRV is thought to have circulated in sheep and goats for a long time before being officially identified.

Nevertheless PPRV spread throughout Africa and reached Asia in the second half of the 20th century. Currently, PPRV circulates in over 70 African and Asian countries and poses a major threat to over 80% of the global sheep and goat populations, a distribution that has made it also a target for eradication. To date, four lineages of PPRV have been classified, based on sequencing of the C-terminal domain of the N gene. As with RPV, this reflects the geographical distribution of this virus across Africa, the Middle East and Asian countries. Lineages I, II and III are endemic in West and East African countries, respectively, while lineage IV is endemic in the Middle East and South Asian countries, although its distribution is increasing. Lineages II and III are thought to have originated independently and at the same time, while lineage IV is endemic in Asia. Worryingly, PPRV has shown evidence of a broadening host range, with lineage IV PPRV recently being detected in camels and saiga antelope, and lineage II in deer. Additionally, evidence of PPRV infection has also been detected in cattle and gazelles.

CDV

CDV is believed to have originated in the Americas before spreading into Europe, Africa and Asia following colonisation. It was initially thought that CDV was restricted to the *Canidae*; however, in the 1990s, CDV outbreaks caused fatalities amongst wildlife species including lions, tigers and leopards. A sudden CDV outbreak in the Serengeti National Park in Tanzania, suspected to have originated in African wild dogs, caused unexpectedly high morbidity and mortality in the African lion and spotted hyena populations. Indeed, CDV outbreaks pose a great threat to endangered species. For example a severe outbreak in the black-footed ferret population, with mortality rates of more than 70%, rendered this species extinct in the wild in the 1980s. More recently, CDV was reported in endangered Ethiopian wolves and it also now poses a major threat to Nicaragua's jaguar population, following transmission from CDV-infected hunting dogs. To date, CDV has been reported to naturally or experimentally infect almost all families of the order *Carnivora*. Significantly, CDV outbreaks have also been reported in monkeys in China and Japan, raising concerns that this virus can cross-over the species barrier to infect primates. Experimental adaptation *in vitro* has shown that CDV can rapidly adapt to use both epithelial and immune human cell receptors.

The worldwide prevalence of CDV has resulted in isolates being categorized into various phylogenetic lineages. CDV lineages are categorized based on H protein variability, with more than 5% amino acid diversity being the cut-off for delineation. Over the last 40 years, 10 lineages of CDV have been described based on this criterion, with the lineages also reflecting geographical distribution: two North American, three European, two South American, two Asian and one South African lineage(s). North America lineage 1 includes the vaccine strains of CDV while North America 2 viruses are known to be currently circulating in the USA; however, recently a third lineage has also been reported in domestic dogs. In South America, Europe lineage 1 strains were predominant until the identification of CDV strains in wildlife in Argentina, which led to the classification of South America lineage 2. The same authors suggested renaming Europe 1 to Europe/South America 1. Furthermore, Espinal *et al.* have also reported the presence of a third lineage in South America in Colombian domestic dogs. In Europe, CDV strains from Europe lineage 3 are currently circulating in Italy, affecting wolf populations in particular, and contributing to a spill-over event in badgers. The first CDV infection in anteaters has recently been reported in Brazil, with these strains clustering in the Europe/South America 1 lineage. Lastly, phylogenetic analysis of Serengeti isolates has revealed that these constitute a different lineage from the currently circulating South African lineage.

Aquatic Mammal Morbilliviruses

PDV was one of the first aquatic morbilliviruses to be identified and, to date, has caused two large outbreaks in European harbor seals. These outbreaks were originally thought to be CDV-related, as an epizootic event was taking place at the same time following contact of infected terrestrial mammals with seals; however, the harbor seals were later shown to be infected with a genetically and antigenically distinct virus that showed similar clinical manifestations. The second aquatic morbillivirus, CeMV was first isolated in 1991 with a host range largely restricted to dolphins, whales and porpoises. To date the exact origin of CeMV remains unknown, however, phylogenetic analysis suggests that CeMV shares a common ancestor with RPV and PPRV, suggesting that its origin might be a spill-over event. CeMV is presumed to be endemic in cetacean populations with an outbreak in pilot whales recently reported in the Canary Islands.

Emerging Morbilliviruses

Recently, a morbillivirus was detected in domestic house cats, firstly in China, with later reports from Japan, the USA and South Africa, suggesting the presence of a previously unidentified morbillivirus, largely restricted to these animals. Phylogenetic analysis based on the six structural proteins revealed that FmoPV clusters together with other morbilliviruses; however, FmoPV is somewhat distinct and less closely related to the other recognized members of the *Morbillivirus* genus. Interestingly, a recent study by Drexler *et al.* showed that bats and rodents may serve as a reservoir for a large number of previously uncharacterized morbilliviruses. The authors isolated multiple viral sequences which upon analysis were closely related to morbilliviruses, yet distinct enough to create their own phylogenetic clusters. This study also identified two bat isolates that were closely related to CDV and PDV, raising concerns of possible zoonotic transmission.

Clinical Features

The following is a summary of the classical clinical signs and symptoms seen in animal morbillivirus infections. A typical acute infection in animals can be classified into five distinct stages: Incubation, Prodromal, Mucosal, Diarrhoeic and Convalescent – a categorisation that corresponds well with the ‘in-tissue’ spread of infection described in the Pathogenesis section below. For RPV infections in cattle, which were often severe, the development of clinical disease was often summarised more succinctly as diarrhoea, dehydration and death. The initial incubation period is followed by a transient pyrexia. Around this period oculo-nasal discharges (associated with virus excretion and consistent with conjunctivitis and rhinitis) begin to develop which can become mucopurulent over time. Similarly, mucosal necrosis develops with erosions and ulcerations in the oral cavity, digestive and/or respiratory tracts. This worsens over time as shedding of necrotic material leads to severe erosions, bloody diarrhoea and a general worsening condition in the animal. Emaciation, dehydration and an associated drop in temperature to sub-normal levels can follow, all contributing to lethality. Other more non-specific signs of infection include restlessness, depression and anorexia as well as shallow and rapid breathing. In pregnant animals infection of the foetus and/or frequent abortion can occur; however, there is little evidence for teratogenic effects or the development of persistently infected ‘carrier states’ in new-borns. The mortality rate in morbillivirus infections can vary greatly, dependent on a number of factors. In immune-naïve herds mortality rates of 100% have been recorded, especially for the ruminant morbilliviruses. However, for other morbilliviruses a significant percentage of infections may be sub-clinical in nature, *e.g.*, CDV infections in domestic dogs. It is known that disease severity varies based on the strain of host as well as its immune status (vaccinated, immunosuppressed or waning maternally-derived immunity). Other complex factors, such as herd immunity levels and geographical endemicity may also contribute to severity in the wild. Variations within the viral sequence strain might also contribute to the development of disease, perhaps best exemplified by the low virulence RPV strains that were circulating in East Africa prior to eradication. In animals that survive an acute infection, one of the hallmarks of morbillivirus infection is a prolonged period of immunosuppression, frequently associated with secondary bacterial infections or indeed viral co-infections. Antigen and viral RNA can persist long after the resolution of acute infection; however, the significance of this to both viral epidemiology and immunosuppression is not well understood.

The progression of disease in morbillivirus-infected animals can also vary between hosts and there are a range of specific clinical signs that appear more specific to one virus than others; however, whether these are the result of virus- or host-specific differences is not well understood. Noticeable differences include a more frequent neural pathology in certain hosts. For CDV and CeMV encephalitis can be prolonged and chronic, with lesions forming in the CNS and brain. This is associated with abnormal behaviour, poor coordination, seizures and possible paralysis and can result in extensive demyelination. CDV-infected dogs can develop old dog encephalitis (ODE) which is reminiscent of the chronic MeV infection in humans, sub-sclerosing pan-encephalitis (SSPE) and many of these neurological symptoms develop long after the resolution of acute infection. Hyperkeratosis is most dominantly seen in CDV-infected domestic dogs; however, keratosis of the flippers, head, trunk, and tail have been reported for aquatic mammal morbilliviruses. In morbillivirus-infected ruminants, digestive pathology is more severe with the Peyer’s patches being particularly badly affected. In the large intestines of ruminants submucosal capillaries running along the crests of the mucosal folds become congested giving rise to zebra-stripes – a pathological hallmark of disease. There are, however, specific differences between the ruminant viruses as well, *e.g.*, PPRV is more likely to cause a primary viral pneumonia with frequent secondary microbial infections involving *Pasteurella* spp. and *Mycoplasma* spp. Significant respiratory infections are also evident in aquatic mammals, where bronchopneumonia is evident as well as necrosis of various tissues accompanied by atelectasis, congestion, edema and emphysema; the presence of parasitic and/or mycotic secondary infections in these animals has also been identified. FeMV infections perhaps represent the greatest outlier and currently there is no clear evidence that the virus utilises the biphasic life cycle described for other morbilliviruses. FeMV infections appear chronic and possibly sub-clinical in domestic cats with the kidneys and urine being associated with virus persistence and transmission, respectively.

Pathogenesis

As discussed previously, morbilliviruses are immuno and epithelio-tropic viruses; tropisms defined by their use of specific proteinaceous receptors. Accordingly, infection of cell-types expressing the two established receptors, SLAMF1 (aka CD150) and Nectin-4, determines the route and progression of disease within the mammalian host. SLAMF1, the immune cell receptor, is found on activated lymphocytes (B and T cells) as well as macrophages and dendritic cell subsets. The physiological role of SLAMF1 is predominately immune cell signalling; however, a role in the innate immune response to Gram-negative bacteria was also recently uncovered. Nectin-4, in contrast, is found on epithelial cells, mainly at mucosal surfaces in the respiratory and digestive tract. Physiologically, Nectin-4 is critical for cellular adhesion, forming an essential component of the adherens junction between polarised epithelial cells.

Morbilliviruses are highly infectious, and despite their enveloped particle, are thought to be capable of persisting in aerosolised droplets or on contaminated fomites or bedding for extended periods of time. For the majority of animal morbilliviruses the primary source of infection is thought to be inhalation of contaminated respiratory droplets. The prevalent model for virus dissemination through the host (summarised in [Fig. 6](#)) is built on various pathogenesis and receptor studies, including animal models of MeV infection. Initially, resident SLAMF1-expressing cells, such as dendritic cells or macrophages in the respiratory tract

Fig. 6 Model of animal morbillivirus spread in an infected host. Virus particles enter *via* the respiratory route (1), with the virus first infecting SLAMF1-positive immune cells in tissues in the upper respiratory tract, perhaps the tonsil (2). Infected immune cells drain to local lymph nodes seeding subsequent rounds of immune cell infection and enabling the virus to reach more remote lymphatic tissues and immune-related organs such as the spleen (3). Immune cell-associated viraemia subsequently allows viral dissemination to other organs, such as the intestine, lungs and trachea (4). In these tissue infection spreads into the epithelial cells of these organs, *via* Nectin-4 mediated entry; a receptor found on the basolateral surface of polarised cells. This second stage of the infection plays a key role in the development of many clinical signs observed in animal morbillivirus infections. Lastly, nascent virions are released into the lumen of the digestive or respiratory tract, allowing spread to naïve animals (5). Of note, the neurological infections seen in some CDV-infected dogs are not illustrated here.

are infected. However, despite high levels of Nectin-4 expression in the oral cavity and upper respiratory tract this receptor is not immediately accessible because adherens junctions are buried on the basolateral surface of polarised cells. Indeed, infected immune cells first migrate to local lymph nodes, leading to a burst of viral replication in resident B and T cells. Subsequently, infected cells migrate from lymphatic tissues into the blood generating a cell-associated viraemia. It is only then, upon contact between morbillivirus-infected immune cells and the basolateral surface of mucosal epithelia that the virus spreads to Nectin-4-positive cells. Replication within epithelial tissues leads to preferential release of nascent virus into the lumen of the respiratory or digestive tract favouring transmission to new hosts. This biphasic life cycle has led to SLAMF1 and Nectin-4 being referred to as the entry and exit receptors, respectively.

This widely accepted model for morbillivirus infection is supported by pathological observations following autopsies of naturally or experimentally infected animals. Morbilliviruses can be detected in the bronchus-associated lymphoid tissue (BALT) and trachea-bronchial lymph nodes within a few days of infection. In addition, a significant incubation period is observed (without epithelial pathology), associated with an acute leucopenia – indicative of localised replication in lymphatic tissues. Marked necrosis and depletion of lymphocytes can be seen in a range of immune tissues such as the spleen and thymus as well as lymph nodes surrounding both the respiratory and digestive tract, where germinal centre B cells are frequently found to be infected. Subsequent virus spread to the epithelium is associated with immune cell infiltration into the lamina propria and degeneration of epithelial cells. Fused epithelial cell syncytia can often be observed as well as intracytoplasmic and intranuclear inclusion bodies.

Diagnosis and Prevention

The control and prevention of morbillivirus disease is of global relevance to human health, agriculture and wildlife. In fact, in many ways, morbillivirus diseases primed many of the modern approaches to veterinary vaccination and epidemic control (see Rinderpest case study below). The varied approaches are summarised in this section.

Certain animal morbilliviruses, such as RPV or PPRV, are notifiable diseases – enabling a co-ordinated response to infection, especially in non-endemic settings. For these viruses in particular there are a multitude of available tests and tools for diagnosing viral infection, as well as advisory information on which samples and tissues to harvest (managed by the World Organisation for Animal Health, OIE). This advice is likely applicable to all morbillivirus infections; however, the availability of validated diagnostic assays may vary. The recommended sites for sampling are swabs from the eye, nose and any obvious mucosal erosions or lesions, as well as uncoagulated blood. As with many infections the aim is to sample and isolate live virus, viral RNA, viral antigen and/or host-specific antibodies. Virus isolation can be made on a broad range of cell-lines, *e.g.*, Veros, where the efficiency of recovery can be boosted by over-expression of one of the cognate receptors, SLAMF1 or Nectin-4. There are various established RT-PCR or RT-qPCR tests to detect viral RNA, whilst viral antigen can be detected by agar gel immunodiffusion, immunocapture ELISA or penside test assays. The isolation of virus-specific antibodies is important for serological and epidemiological monitoring, as well as the assessment of vaccination responses. Of note, all morbilliviruses appear to be mono-serotypic in nature enabling sero-surveillance. Various established tests are available including virus neutralisation tests (VNTs), indirect ELISAs and competitive ELISAs, all of which target immune responses to the F, H and/or N protein. Sequencing of viral isolates, often targeting the *N*, *F* or *H* genes, has proved beneficial for phylogenetic characterisation and tracking of outbreaks.

Basic approaches to limit the spread of disease are effective at controlling morbillivirus outbreaks. In non-endemic settings the segregation of animals and culling of infected and contact individuals has proven effective, along with adequate disposal of infected carcasses. Often this is not practical in non-endemic or wildlife settings, where vaccination is the only realistic option. The best animal vaccines must have the following properties: They must be efficacious and safe in all animals and breeds, immunity must be easily testable *in vitro*, they must not be immunosuppressive, and finally they should provide lifelong or near-lifelong immunity. Fortunately, many of the licenced morbillivirus vaccines share these properties, the most widely used of which are live attenuated variants. The two commonly used CDV vaccine strains were derived from adaptation to ferrets, chicken embryos and later chicken cell lines (Onderstepoort) or canine kidney cell lines (Rockburn). Whilst these are widely, and successfully, used in dogs their efficacy in wildlife is less clear, with examples of vaccine-associated virulent disease. The difficulties associated with testing and using vaccines in wildlife also means that few vaccine trials have been performed in aquatic mammals, although there is evidence of CDV vaccines providing cross-protective immunity. The other widely used morbillivirus vaccines are the live attenuated PPRV vaccines, generated following serial passage of field strains in tissue culture (Veros). Recently, researchers have demonstrated that the two most widely used vaccines are efficacious against all lineages of circulating PPRV, supporting their use in future control and eradication campaigns. Despite the availability of efficacious vaccines there is a requirement for next generation tools. For example, a vaccine that would allow epidemiologists and veterinarians to distinguish infected from vaccinated animals (DIVA) would prove beneficial in a post-outbreak or eradication setting. Researchers have investigated this by modifying viral epitopes, using alternative viral vectors or recombinant protein platforms to express immunogens or indeed making recombinant morbilliviruses and there is great promise that one such vaccine will soon come to the market, likely for PPRV. Lastly, it is worth noting that recombinant morbilliviruses are also used as vectors themselves to deliver and express antigens from other important viruses, *e.g.*, a CDV expressing Rabies G protein.

Treatment

In general supportive care revolves around maintaining adequate hydration and the avoidance of secondary bacterial infections. Although there are no licenced antivirals for treating sick animals, there are a number of candidate antiviral compounds that have shown efficacy in the lab either by blocking fusion or inhibiting the polymerase.

Rinderpest Eradication: A Success Story

Although RPV was declared eradicated by the FAO and OIE in 2011 the history of control of this disease goes back hundreds of years. Historically, outbreaks of RPV in Europe and Asia are thought to have originated in the Caspian basin (presumably brought in by or with marauding armies). To an extent, the severity and frequency of these outbreaks is thought to have precluded the development of sustainable bovine agriculture. However, in 1711, following RPV disease in the papal herds, Pope Clement XI ordered a physician, Dr. Lancisi, to investigate the issue. He implemented some of the first detailed epidemic control strategies in animals including movement restriction, slaughter and burial of carcasses in lime. The success of this strategy was quickly adopted by other countries in Europe to control RPV infections; many of these approaches are still in use today. Training in the implementation of these strategies led to the development of the first veterinary school (Lyon, France 1761) as well as state veterinary services, with other countries in Europe soon following suit. Rinderpest was also instrumental in establishment of the OIE, while RPV was one of the first issues tackled by FAO in inaugural meetings. The impact of RPV on wildlife should also not be overlooked, as this virus caused devastating epidemics in wild ungulates, especially in Africa. Interestingly, wildlife were initially thought to be the source of infections; however, following the successful removal of RPV from cattle populations in the Serengeti ecosystem, the buffalo and wildebeest populations soared. The history of RPV vaccines tracks a shift from treatment to prevention and finally eradication. Initial vaccinations involved immunization with sera from convalescent animals. This was replaced by killed vaccines and then ultimately live attenuated viruses adapted to animals: goats, rabbits and eggs but later tissue culture

– primary calf kidney cultures. The history and politics of RPV eradication is a fascinating area summarised excellently elsewhere (see further reading); however, the key factors that led to these live attenuated vaccines being successfully used to eradicate RPV are as follows: There was a limited geographical distribution of the disease and no latency or persistence. In addition, infected animals had a short infectious period and transmission was reliant on direct or close indirect contact. This, combined with a safe universal vaccine, usable in all animals and providing lifelong immunity contributed to the success of a global approach led by international organisations with a clear mandate and unified strategy. Many of these criteria apply to PPRV and the FAO and OIE have recently launched a global strategy for PPRV eradication. Whilst eradication is also a meaningful target for the human morbillivirus MeV it seems unlikely that CDV or any of the aquatic mammal morbilliviruses are realistic targets, given their global distribution and more complicated host-range.

Glossary

Cell mediated immunity The part of the immune response that is directly mediated by cells such as cytotoxic T-lymphocytes.

Humoral immunity The part of the immune response that is mediated by antibodies.

Immunohistochemistry Using antibodies to identify proteins within histological sections.

In situ hybridization Using antisense probes to identify DNA or RNA within histological sections.

Oncoproteins Proteins that promote cell growth and division.

Open reading frame A section of nucleotide sequences between a start and a stop codon.

Papilloma While it is acknowledged that papillomas can either be papillomavirus-induced hyperplastic lesions or non-papillomavirus-induced benign neoplasms of the epithelium, in the text the term 'papilloma' is used to indicate an area of focal epithelial thickening caused by papillomavirus infection. The term papilloma is therefore used to describe a 'wart' in human medicine.

Retinoblastoma protein A protein that controls cell division. Loss of retinoblastoma protein will favor cell division.

Viral capsid The protein shell of a virus.

Classification

The *Papillomaviridae* family includes two subfamilies, the *Firstpapillomavirinae* and the *Secondpapillomavirinae*. The *Firstpapillomavirinae* currently contains 51 genera while only one genus is currently classified within the *Secondpapillomavirinae* subfamily. Genera in the *Firstpapillomavirinae* are named using the Greek alphabet. As there are now more papillomavirus genera than letters in the Greek alphabet, the prefixes dyo- and treis- have been used. For example the deltapapillomavirus genus was the fourth genus established and this was prior to the dyodeltapapillomavirus genus which was established prior to the treisdeltapapillomavirus genus. Within the *Secondpapillomavirinae* subfamily, genera are named according to the Semitic abjads (an abjad is similar to an alphabet, except only consonants are represented). Alefpapillomavirus is only genus currently within the *Secondpapillomavirinae* subfamily.

Knowledge of the genera of papillomaviruses is useful as papillomaviruses within each genus often have closely related hosts. Additionally papillomaviruses within the same genera often have similar biological properties and therefore usually cause similar diseases. For example papillomaviruses in the Lambdapapillomavirus genus all infect carnivores and cause proliferative papillomas, most frequently in the oral cavity.

Within genera, the papillomaviruses are further subdivided into numerically-named species. Currently there are 133 papillomavirus species within the 51 papillomavirus genera. Papillomaviruses within the different species can be expected to have the same, or closely related, hosts and similar biological behaviors. For example, within the deltapapillomaviruses, the species 4 deltapapillomaviruses all cause fibropapillomas in domestic cattle while the species 1 lambdapapillomaviruses all cause oral papillomas in felids including domestic cats, snow leopards, bobcats, and lions.

Within the species, papillomaviruses are subclassified into individual papillomavirus types. Each papillomavirus type is named sequentially using the scientific name of the host species. For example, the sixth fully classified papillomavirus of domestic cattle is *Bos taurus* papillomavirus type 6, which is a species 1 xipapillomavirus within the xipapillomavirus genus. With the notable exception of the bovine species 4 deltapapillomaviruses, papillomaviruses are highly species-specific. Around 500 individual papillomavirus types have been fully classified, including around 175 from the non-human species. Papillomaviruses have been identified in virtually every species that has been intensively studied including cattle, horses, dogs, cats, sheep, deer, rabbits, bears, sea lions, dolphins, primates, birds, a variety of laboratory and free-ranging rodents, bats, snakes, and turtles. Most species are likely to be infected by multiple papillomavirus types from multiple papillomavirus genera and further research will undoubtedly identify many more papillomavirus types in animals.

Classification of papillomaviruses has traditionally been using the genetic sequence of the L1 open reading frame (ORF) (Fig. 1(a)). Viruses of different subfamilies have less than 45% similarity in their L1 ORF while papillomaviruses in different genera have less than 60% similarity. Papillomaviruses with less than 70% similarity are considered to be in different species and less than 90% similarity is present between papillomaviruses of different types. While this scheme is simple, many viruses will show overlap between multiple different genera and species, making classification difficult. To overcome these areas of overlap, papillomaviruses are additionally classified based on their host species and the type of lesions that they cause.

As papillomaviruses tend to infect either mucosal or cutaneous epithelium, human papillomaviruses are also classified into mucosal or cutaneous types. While the same is likely to be true in animals, this classification is not widely used in veterinary medicine. In humans, papillomaviruses are also classified based on the likelihood that they will cause cancer. Therefore the 'low-risk' alphapapillomaviruses cause warts that spontaneously resolve and rarely, if ever, progress to cancer. In contrast, the 'high-risk'

Fig. 1 (a). Schematic representation of select papillomavirus genera (courtesy Dr. Neroli Thomson, Massey University, New Zealand). (b). Genetic organization of *Felis catus* papillomavirus type 2 and human papillomavirus type 16 showing open reading frames within the viral genome and the long control region (LCR; courtesy of Dr. Neroli Thomson, Massey University, New Zealand).

Table 1 Summary of papillomaviruses that have been detected in five domestic animal species. It should be noted that not all papillomavirus types within a genus will cause all the associated lesions listed. For example, *Canis familiaris* papillomavirus (CPV)-17 is the only canine Taupapillomavirus type associated with oral SCCs and only CPV-2 and -7 have been associated with cutaneous papillomas. Additionally, while papillomaviruses are listed as being associated with lesions, for many the role of the papillomavirus in lesion development still remains unproven. SCC, squamous cell carcinoma; BISC, Bowenoid *in situ* carcinoma; BPV, *Bos taurus* papillomavirus; OaPV, *Ovis aries* papillomavirus; EcPV, *Equus caballus* papillomavirus; CPV, *Canis familiaris* papillomavirus; FcaPV, *Felis catus* papillomavirus

Species	Papillomavirus genus	Papillomavirus types	Predominant associated lesions
Cattle	<i>Delta</i>	BPV-1, -2, -13, -14	Cutaneous and esophageal fibropapillomas Bladder neoplasia
	<i>Xi</i>	BPV-3, -4, -6, -9, -10, -11, -12, -15, -17, -20, -23, -24	Cutaneous and upper alimentary papillomas Upper alimentary SCC
	<i>Epsilon</i>	BPV-5, -8	Cutaneous papilloma
	<i>Dyoxi</i>	BPV-7	Cutaneous papilloma
	<i>Dyokappa</i>	BPV-16, -18, -22	Cutaneous papilloma
	Unclassified	BPV-19, -21	Cutaneous papilloma
Sheep	<i>Delta</i>	OaPV-1, -2, -4	Cutaneous fibropapilloma
	<i>Dyolambda</i>	OaPV-3	Cutaneous SCC
Horses	<i>Zeta</i>	EcPV-1	Cutaneous papilloma
	<i>Dyoiota</i>	EcPV-2, -4, -5	Penile papilloma Penile SCC Aural plaque
	<i>Dyorho</i>	EcPV-3, 6, 7	Aural plaque
	Unclassified	EcPV-8	Cutaneous papilloma
	<i>Delta</i>	BPV-1, -2, 13	Equine sarcoid
Dogs	<i>Lambda</i>	CPV-1, -6	Oral papillomas Cutaneous papillomas
	<i>Tau</i>	CPV-2, -7, -13, -17, -19	Cutaneous papillomas Oral SCC
	<i>Chi</i>	CPV-3, -4, -5, -8, -9, -10, -11, -12, -14, -15, -16, -18, -20	Viral pigmented plaques Cutaneous SCC
Cats	<i>Lambda</i>	FcaPV-1	Oral papillomas
	<i>Dyotheta</i>	FcaPV-2	Viral plaques/BISC Cutaneous SCC
	Unclassified	FcaPV-3, -4, -5	Viral plaques/BISC
	<i>Delta</i>	BPV-14	Feline sarcoid

alphapapillomaviruses cause around 5% of all human cancers. While papillomaviruses are not commonly subdivided into 'low' and 'high' risk categories in veterinary medicine, there is increasing evidence that a subset of papillomavirus types cause cancer in animals.

The papillomavirus types that are currently recognized from the major domestic species are contained in [Table 1](#).

Virion Structure

Papillomavirus virions are non-enveloped and around 55 nm in diameter. The viral capsid consists of 360 copies of the L1 protein which are arranged in 72 pentamers (five-sided arrays) and around 12 copies of the L2 protein. Each capsid contains one copy of the papillomavirus DNA although both "empty" and "full" virus particles can be seen by electron microscopy. Papillomaviruses are resistant to diverse environmental insults and infectivity survives lipid solvents and detergents, low pH, and high temperatures.

Genome

The genome consists of a single molecule of circular double-stranded DNA that is typically around 7500 bp in length although the genome of individual papillomavirus types ranges from 5748 bp to 8607 bp. Several different translational strategies are utilized to enhance the limited coding capacity of the papillomavirus genome.

The genome encodes 6–9 proteins depending on the individual papillomavirus type. These proteins are subdivided into the early (E) and late (L) proteins ([Fig. 1\(b\)](#)). The E proteins are non-structural proteins and have important regulatory and replicative

Fig. 2 Schematic representation of papillomaviral replication with stratified epithelium. Arrows indicate where the predominant layers of the epithelium at which each papillomaviral protein is produced and where papillomaviral DNA replication occurs (courtesy Dr. Neroli Thomson, Massey University, New Zealand).

functions. The E1 protein is a viral DNA helicase and is responsible for unwinding the double-stranded DNA. The main function of the E2 protein is to control the papillomavirus replication cycle. As will be discussed, replication of papillomaviruses is closely coordinated with epithelial cell replication and differentiation and the E5, E6 and E7 proteins alter the normal regulation of epithelial cells to maximize papillomavirus replication. As these proteins can promote cell division and therefore potentially cause neoplastic transformation of a cell, they are often referred to as 'viral oncoproteins'. In the majority of papillomavirus types, E7 is considered to be the protein that most significantly influences epithelial cell regulation. The E7 protein influences cell division by binding, and degrading, the retinoblastoma protein, an important cell cycle checkpoint. The E7 of most papillomavirus types has a retinoblastoma binding site (LXCXE) although binding to retinoblastoma protein can occur even without this site, possibly due to poorly-defined alternative pRb binding sites within the E7 carboxyl-terminal domain. In contrast, promotion of cell regulation by bovine deltapapillomaviruses appears to be primarily through interactions between the E5 protein and the platelet-derived growth factor- β receptor. The two L proteins form the viral capsid and these are only expressed close to the completion of the viral replication cycle.

Life Cycle

Infection by most papillomavirus types is currently believed to be restricted to stratified squamous epithelium. This is because papillomavirus replication is dependent on, and intimately linked to, the growth and differentiation of these epithelial cells (Fig. 2). Infection by a papillomavirus occurs when micro-trauma allows the papillomavirus to interact with the basement membrane, which then facilitates viral entry into a basal cell. The papillomavirus genome and some viral E proteins then enter the nucleus resulting in the production of 10–200 episomal copies of viral genomic DNA. As basal cells replicate, the episomal DNA spreads through the basal cell population and infection is maintained indefinitely within the infected epithelium. During this phase of replication, the papillomavirus does not significantly alter normal epithelial cell regulation and such infections are asymptomatic. While the infection is maintained within the host, viral replication does not occur and the infection at this stage is not infective.

For a papillomavirus to complete its life cycle, it has to be present within a basal cell that undergoes terminal differentiation. However, once a basal cell has terminally differentiated, it loses the ability to divide, resulting in degradation of the nucleus. As replication of the papillomavirus DNA is dependent on the host cell nuclear machinery, a key feature of papillomaviruses is their ability to prevent cells from leaving the S-phase of the mitotic cycle. By ensuring the infected keratinocytes keep dividing, not only does the papillomavirus retain the nuclear machinery within the cell, but also amplifies the infection by ensuring that each dividing keratinocyte contains replicating papillomavirus. As the infected keratinocytes approach the surface of the epithelium viral capsids are produced and virions are assembled. An infected cell may produce 10,000–100,000 new virus particles. Papillomaviruses do not cause cell lysis and virions are only released after the epithelial cell has been sloughed from the epithelial surface and degraded.

Replication of the papillomaviral DNA begins when an initiation complex binds to a single unique origin of replication resulting in unwinding of the DNA. A single DNA strand is synthesized continuously in the direction of unwinding with an additional DNA strand synthesized discontinuously in the opposite direction. As replication proceeds, the torsional strain created by the unwinding of the parental strands of DNA is released by the E1 protein. Bidirectional replication proceeds around the full genomic DNA circle resulting in the formation of two new strands of circular DNA.

Infection by papillomaviruses can result in a variety of clinical manifestations that include asymptomatic infection, papillomas (warts), viral plaques, and neoplasia. The manifestation of infection is largely dependent on whether or not the papillomavirus is replicating and the ability of the viral oncoproteins to promote epithelial cell division. Most papillomavirus infections are asymptomatic. Such asymptomatic infections may be due to a papillomavirus infection remaining latent and not replicating.

Alternatively, papillomavirus infections may remain asymptomatic when replication by the papillomavirus occurs only at a slow rate. Slow viral replication only mildly increases epithelial cell proliferation and visible changes in the epithelium will not develop. Papillomavirus infections that are characterized by slow viral replication generally stimulate no, or a weak, immune reaction. Therefore such infections may persist, resulting in the production of small numbers of infectious virions throughout the life of the host. In contrast, if the papillomavirus is able to stimulate marked epithelial proliferation, the thickened epithelium will become folded resulting in a visible papilloma. By stimulating such marked epithelial proliferation large numbers of infective virions are produced. However, the changes to the epithelium will be detected by the host resulting in an immune response, regression of the papilloma, and prevention of further viral replication. Viral plaques tend to be caused by papillomaviruses types that are normally asymptomatic, but an inability of the host to limit the rate of replication enables them to stimulate greater epithelial proliferation. Papillomaviruses can also predispose to neoplasia. The likelihood that a papillomavirus will cause neoplasia is not dependent on the degree of epithelial proliferation that is able to be induced by the papillomavirus. Indeed the human papillomaviruses that cause warts rarely cause cancer.

Epidemiology

There are currently few studies investigating the epidemiology of papillomavirus infections in animals. However, it appears likely that there are significant differences in the epidemiology of infection between papillomaviruses that are generally asymptomatic and papillomaviruses that cause papillomas.

The overwhelming majority of papillomaviruses are well adapted to their hosts and infections by these papillomavirus types typically remain asymptomatic. These papillomaviruses infect a high proportion of individuals with infection being from the dam, either during the birth process or due to the close contact between the mother and newborn shortly after birth. While direct contact is the most accepted mechanism of transfer, there is some evidence that transplacental transfer of papillomaviruses could be possible. Examples of papillomaviruses that are transmitted this way include the human beta-papillomaviruses that ubiquitously infect the skin of people and *Felis catus* papillomavirus type 2 which can be detected in almost all cats from very early in life.

Papillomaviruses that cause papillomas appear to have a different epidemiology as evidence suggests that papilloma development occurs when an animal is first infected by the papillomavirus. This infection could be the result of direct contact or indirect contact from a fomite. The initial infection results in a period of rapid virus replication that results in the development of a visible papilloma. Due to the large number of virions produced in a papilloma, an animal is likely to be highly contagious at this time. However, after a variable period of time, the body mounts a cell-mediated immune response against the papilloma, inhibiting viral replication and causing papilloma regression. Due to the ability of the infection to be maintained within the basal cells, it is likely that the infection is never completely resolved although it appears that few, if any, infectious virions are produced. This method of infection and disease development is illustrated by the 'outbreaks' of papillomas that have been rarely reported in animals.

Clinical Features

Infection by papillomaviruses can result in four distinct clinical manifestations that will be described separately. Due to differences between the species, these manifestations of papillomaviral disease will also be described separately for ruminants, horses, dogs, and cats. It should be noted, many other non-human species develop lesions due to papillomavirus infection and the list of species herein is not intended to be comprehensive.

Papillomas

Papillomas are the result of papillomavirus-induced thickening and folding of the epithelium. They mostly develop in young animals, presumably at the time of first infection by the causative papillomavirus type. Humoral antibodies are formed that protect the animal from additional infection by the papillomavirus type and, after a variable amount of time, the body mounts a cell-mediated immune response that causes spontaneous regression of the papilloma. The infection is probably not completely cleared and later immunosuppression may allow the papillomavirus to cause further papillomas. As papillomas typically regress and do not contain mutations within the cell DNA, they are not considered neoplasms. Papillomavirus-induced papillomas are commonly referred to as 'warts' in humans.

Ruminants

Papillomas in cattle are common with most animals developing these at some time in their lives. Papillomaviruses can be spread by direct contact or by fomites such as contaminated milking equipment, rubbing posts or wire fences. Sexual transmission of papillomavirus-induced genital papillomas is likely.

Papillomas in cattle can be subdivided into squamous papillomas that consist solely of proliferating epithelium and fibropapillomas in which there is proliferation of both the overlying epithelium and the underlying dermal fibroblasts. Cattle develop mucocutaneous papillomas and papillomas of the upper alimentary tract.

Mucocutaneous papillomas of cattle are most common around the head, but also commonly develop on the penis, vulva, and teats (**Fig. 3(a)**). As recent studies have revealed that most papillomas contain numerous BPV types, whether or not papillomas in particular locations are more likely to be caused by a specific BPV type is unknown. However, it appears likely that fibropapillomas are caused by infection with the deltapapillomavirus types, predominantly BPV-1 and -2. Rarely florid persistent mucocutaneous papillomas can be present and these can cause morbidity or mortality by interfering with vision or predisposing to secondary infection. It is currently unknown why some cattle appear unable to make an effective cell-mediated immune response against the papillomas. As these animals are invariably slaughtered, it is also unknown whether these warts would eventually have spontaneously resolved or would have progressed to neoplasia.

Upper alimentary papillomas develop from the caudal aspect of the oral cavity to the rumen. They are subdivided into squamous papillomas and fibropapillomas that are thought to be caused by BPV-4 and BPV-2 respectively. These papillomas typically remain small and self-resolve and clinical disease due to these papillomas is extremely rare. However, in animals that are exposed to the immunosuppressive and carcinogenic chemicals in bracken fern, upper alimentary squamous papillomas can become persistent and these papillomas can undergo neoplastic transformation.

Sheep develop cutaneous squamous papillomas and fibropapillomas most commonly around the muzzle, feet, and mammary gland. As with other species, the papillomas spontaneously resolve. Sheep are infected by three deltapapillomavirus types, although it is currently unknown which of these cause fibropapillomas. Fibropapillomas of the mammary glands have also been reported in goats.

Horses

Equine papillomas can be subdivided into those of the genitals and those that develop in other mucocutaneous areas. All are squamous papillomas and fibropapillomas are not recognized in horses.

Genital papillomas in horses are thought to be caused by *Equus caballus* papillomavirus type 2 (EcPV-2). Papillomas are more common in males and usually develop on the free part of the penis (**Fig. 3(b)**). Unlike papillomas in other species, equine genital papillomas most often develop in middle-aged or older animals. It is currently unknown how EcPV-2 is spread between horses,

Fig. 3 (a). Teat papillomas on an Angus cow. Multiple filiform squamous papillomas are visible. (b). Penile papillomas on a horse. Numerous papillomas are present and these have extended to involve the majority of the free part of the penis (courtesy Dr. Richard Malik, Centre for Veterinary Education, University of Sydney, Australia). (c). Oral and cutaneous papillomas on a dog. Despite their large size and number, such papillomas rarely cause discomfort to the dog. (courtesy Dr. Stephen White, University of California at Davis, California, USA). (d). Pigmented plaques on a dog. Multiple sessile darkly pigmented plaques are visible scattered over the legs of this dog (courtesy Dr. Mark Turnwald, Belmont Veterinary Clinic, North Shore City, New Zealand).

but as papillomas develop in castrated horses, sexual transmission is unlikely. The biological behavior of equine genital papillomas is currently unresolved with some spontaneously resolving, others becoming numerous and persistent, and a proportion progressing to penile squamous cell carcinoma (SCC).

Non-genital warts in horses are common and are thought to be predominantly caused by EcPV-1. They are most common in younger horses on the muzzle, lips, distal limbs, and eyelids. Papillomas are typically multiple and individual papillomas can coalesce into a single large mass. Non-genital papillomas in horses typically regress within 3 months and persistent infections or progression to neoplasia appears to be extremely uncommon.

Dogs

Papillomas are common in dogs and are subdivided into those of the oral cavity and those of the skin. The majority of oral papillomas are believed to be caused by *Canis familiaris* papillomavirus type 1 (CPV-1, formerly canine oral papillomavirus, COPV). Oral papillomas typically develop in younger dogs and the exophytic vegetative lesions can be multiple and extensive (Fig. 3(c)). However, despite the spectacular clinical appearance, it is rare for papillomas to interfere with eating or breathing by the animal. Most cases will spontaneously resolve within 3 months, although around 30% of papillomas will persist for longer and complete resolution can take up to a year in some cases. There are rare reports of persistent canine oral papillomas and these probably develop due to an ineffective papillomavirus-specific cell-mediated immune response. Such papillomas may be pre-disposed to progression to oral SCC, although this appears to be an extremely rare event.

Canine cutaneous papillomas have been associated with CPV-1, -2, -6, and -7. They are most common in young dogs and affected dogs often develop multiple papillomas. Papillomas develop most frequently in areas that are more likely to have skin abrasions such as the face, ears, and extremities. Canine cutaneous papillomas are further subdivided into exophytic papillomas in which the folded epidermis protrudes above the surface of the skin and inverted papillomas in which the folded epithelium is contained within a central depressed cup-shaped structure. Both exophytic and inverted papillomas are expected to spontaneously regress and it is currently uncertain whether these two lesions are caused by different papillomavirus types. Progression of a cutaneous papilloma to a SCC appears to be extremely rare in dogs.

Cats

Domestic cats are unusual because both cutaneous and oral papillomas are extremely rarely reported. Feline oral papillomas appear as clusters of small pale flattened plaques on the underside of the tongue. These papillomas are thought to be caused by FcPV-1. They are not associated with clinical signs of disease and probably spontaneously regress.

Viral Plaques

Viral plaques are much less common than papillomas. They probably develop when the host is unable to suppress infection by a normally asymptomatic papillomavirus type. The failure to inhibit papillomavirus replication results in moderate epithelial thickening and the development of a plaque. As the lesions do not necessarily develop when the animal is first infected, plaques tend to develop on older animals than papillomas which typically develop in younger animals. While spontaneous resolution of plaques can occur, they can persist over a long period of time and some may progress to SCCs.

Horses

Horses develop precancerous plaques of the penis and aural plaques within the concave surface of the ear pinna. Penile plaques are thought to be caused by EcPV-2 and probably represent an intermediate lesion between a papilloma and a SCC. Aural plaques have been associated with EcPV-3, -4, -5 and -6 with the papillomaviruses thought to be spread between horses by species of black flies (*Simulium* spp.). The prevalence of aural plaques is not known and it is possible many horses have these lesions without their owners seeking veterinary attention. Aural plaques can develop on horses of any age and consist of multiple discrete grey-white, roughened papules that can coalesce to form plaques up to several cm in diameter. Aural plaques may be unilateral or bilateral and are typically only a cosmetic concern. Aural plaques do not regress spontaneously, but have not been reported to progress to SCC.

Dogs

Canine pigmented plaques are thought to be caused by a number of closely-related Chipapillomavirus types. Some breeds of dogs, in particular Pugs and Vislas appear to be predisposed to pigmented plaques suggesting a breed-specific failure in normal suppression of replication by these papillomavirus types. Dogs receiving immunosuppressive therapy are also at increased risk for plaque development, although plaques often develop on dogs with no identifiable immunosuppression. Plaques are typically dark, multiple, and 1–10mm in diameter. They are most common on the ventrum and medial aspects of the limbs (Fig. 3(d)). Canine pigmented plaques are considered cosmetically undesirable, but usually do not cause significant morbidity. There are rare reports of progression to SCC although it is currently unknown whether or not plaques caused by specific papillomavirus types are more likely to progress to neoplasia.

Fig. 4 (a). Pigmented viral plaques/Bowenoid in situ carcinomas on the face of a domestic short haired cat. Two lesions are visible on the face of this cat (arrows; courtesy Dr. Richard Malik, Centre for Veterinary Education, University of Sydney, Australia). (b). Papillomas and squamous cell carcinomas of the penis of a horse. The penis of this horse is covered by papillomatous growths, some of which have progressed to a squamous cell carcinoma. (c). Viral plaques/Bowenoid in situ carcinomas and squamous cell carcinomas on a Devon Rex cat. Histology was consistent with the squamous carcinomas developing from pre-existing viral plaque/Bowenoid in situ carcinomas. Some lesions were covered by a thick layer of keratin (arrow; from Munday, J.S., Benfell, M.W., French, A., Orbell, G.M., Thomson, N., 2016. Bowenoid in situ carcinomas in two Devon Rex cats: Evidence of unusually aggressive neoplasm behavior in this breed and detection of papillomaviral gene expression in primary and metastatic lesions. *Veterinary Dermatology* 27, 215–e55, with permission). (d). Equine sarcoid. This sarcoid developed close to the eye of this 3-year-old horse (arrow; courtesy Dr. Luca Panizzi, Massey University, New Zealand).

Cats

Papillomavirus-induced cutaneous plaques in cats have historically been subdivided into viral plaques and Bowenoid *in situ* carcinomas (BISCs). However, as transitional lesions between the two lesions have been reported, they are best considered different severities of the same disease process. Feline viral plaques/BISCs are most often caused by FcPV-2. Most cats are infected with FcPV-2 shortly after birth and disease development appears to be primarily determined by, as yet poorly understood, host factors. Viral plaques/BISCs are uncommon in cats and usually develop in middle-aged or older animals. Lesions are most common on the head and neck of cats and can be single or multiple (**Fig. 4(a)**). Lesions are typically pigmented, mildly raised, and hairless. More advanced lesions can be ulcerated or covered by thick scaling. Lesions can spontaneously resolve, be persistent without progressing, or slowly increase in size and number. In addition, viral plaques/BISCs are pre-neoplastic and all viral plaques/BISCs should be carefully monitored for progression to a SCC. Viral plaques/BISCs tend to develop in Devon Rex and Sphinx cats at an earlier age and these lesions are predisposed to rapid progression to highly metastatic SCCs in these breeds.

Squamous Cell Carcinomas

In humans, papillomaviruses cause around 5% of all cancers including almost all SCCs of the cervix and 20%–30% of oral SCCs. The papillomaviruses that cause these cancers are a select group of sexually-transmitted ‘high-risk’ alpha papillomavirus types. A key feature of these papillomaviruses is the ability of their E6 proteins to prevent accurate replication of epithelial cell DNA and to inhibit cell apoptosis. This predisposes the proliferating epithelial cells to developing genetic mutations which can result in the development of neoplasia. While papillomaviruses in the domestic species have been associated with neoplasia development, the role of the papillomavirus in cancer development and the mechanisms by which the papillomaviruses cause neoplastic transformation are much less well understood.

Ruminants

Vulval papillomas have been reported to progress to SCCs in cattle that have been exposed to high levels of ultraviolet (UV) light. However, it is currently unknown whether or not the vulval papillomas are caused by papillomavirus infection and there is currently little evidence that papillomaviruses cause skin cancer in cattle.

Upper alimentary tract SCCs are extremely common in cattle that ingest bracken fern. As these SCCs can develop within a pre-existing papilloma, it is possible that BPV-4 could influence the development of these cancers. However, the precise role of the papillomavirus is currently uncertain and PV DNA is not detectable in the SCCs. Furthermore, bracken fern has directly carcinogenic properties suggesting that ingestion of bracken fern could be a more significant factor in the development of cancer than the presence of the papillomavirus. The critical role of bracken fern is supported by the rarity of upper alimentary tract SCCs in cattle that are not exposed to bracken fern.

Cutaneous squamous cell carcinomas in sheep were first proposed to be influenced by papillomavirus infection in 1982 when it was observed that some SCCs developed as a progression from a papilloma and that some SCCs contained PV particles. More recently, *Ovis aries* papillomavirus type 3 (OaPV-3) DNA and gene expression was found more frequently in a series of ovine cutaneous SCCs than in non-neoplastic samples of skin. Current evidence suggests that OaPV-3 could be a significant co-factor with UV light in the development of cutaneous SCCs in sheep. However, as SCCs rarely develop in sheep in the absence of high levels of solar radiation, it is difficult to determine the relative importance of papillomavirus infection and UV light in the development of these lesions. It is also impossible to exclude that higher rates of OaPV-3 are present within the SCCs simply because these cancers provide a more permissive environment for papillomavirus infection.

Horses

Penile SCCs are associated with EcPV-2 infection in horses. Currently the mechanisms by which EcPV-2 causes neoplasia are poorly understood. However, it is hypothesized that a high proportion of penile SCCs develop due to progression of a virally-induced papilloma to a precancerous plaque and subsequently to an invasive cancer (Fig. 4(b)). The degree to which EcPV-2 promotes the progression from papilloma to cancer is uncertain and it is possible that additional cofactors are required for neoplasm development. While both smegma and exposure to sunlight have been suggested as potential co-factors, there is currently little evidence supporting either as significant in the development of penile cancer in horses.

In addition to penile SCCs, there is some evidence that EcPV-2 may also cause a proportion of vulval and oropharyngeal cancers in horses, although currently too few cases have been evaluated to draw conclusions about the role of the papillomavirus in these neoplasms.

Dogs

Cutaneous viral plaques and papillomas have occasionally been reported to progress to SCCs in dogs, although the overwhelming majority of cutaneous SCCs in this species do not appear to be caused by papillomavirus infection.

There are just two reports of oral SCCs being influenced by papillomavirus infection in dogs. In one case, CPV-17 was found within multiple oral plaques and SCCs in a dog. These lesions contained histological evidence of viral replication suggesting that the papillomavirus was the cause of the lesions. Interestingly, CPV-17 has not subsequently been detected in any canine lesion. In the second report a dog had oral papillomas for over 18 months before one progressed to an invasive SCC. Overall, as with cutaneous SCCs, evidence currently suggests that papillomaviruses are not a significant cause of oral SCCs in dogs.

Cats

Papillomaviruses were first associated with feline cutaneous SCCs in 2008 when FcaPV-2 DNA was amplified significantly more frequently from SCCs than from non-neoplastic skin samples. Subsequent evidence has suggested that papillomaviruses could influence the development of 33%–45% of feline cutaneous SCCs. A papillomavirus etiology of a SCC may be most likely for a cancer that develops in skin that is protected from sunlight and it is possible that these SCCs could develop from a pre-existing viral plaque/BISC (Fig. 4(c)). The role of papillomaviruses in SCCs that develop in sun exposed skin is less clear. In people there is good evidence that papillomaviruses and sunlight act as co-factors in the development of SCCs and the same could be true in cats. However, as papillomaviruses commonly asymptotically infect skin, it is currently not possible to definitively exclude the papillomaviruses being present in the SCCs simply because they provide a more permissive environment.

While PV DNA is detectable in a small proportion of feline oral SCCs, there is no evidence that PVs are a significant cause of these neoplasms.

Rabbits

Infection of cottontail rabbits with *Sylvilagus floridanus* papillomavirus type 1 (formerly Shope's papillomavirus, cottontail rabbit papillomavirus, CRPV) causes multiple papillomas which progress to SCCs in around a quarter of rabbits. The consistent development of papillomas and cancer due to papillomavirus inoculation enabled rabbits to be used as an animal model during the development of HPV vaccines.

Sarcoids

Sarcoids are proliferations of fibroblasts that are induced by cross-species infection by bovine deltapapillomaviruses. Sarcoids do not metastasize, but tend to be invasive making complete excision difficult.

Horses

Sarcoids have been reported in horses, donkeys, mules and zebras and are the most common skin tumor of equids worldwide. Sarcoids can be single or multiple and may occur anywhere on horses but are more common on the head, neck, and limbs (**Fig. 4(d)**). They often develop at sites of previous surgery or trauma. Sarcoids are most common in young to middle-aged horses and breed predispositions in Quarter horses, Appaloosas and Arabians have been described.

Sarcoids are thought to be caused by infection with BPV-1, -2 or -13, although sarcoids cannot be induced experimentally by inoculation with these papillomaviruses. It is currently not clear whether BPVs are transmitted from infected cattle, from infected horses, or from both. Horses have historically been considered dead-end hosts of BPV infection, with early studies detecting only BPV DNA in dermal fibroblasts, but never infectious BPV virions. However, expression of the BPV L1 gene has been detected in sarcoids, suggesting the possibility of viral replication within the lesion. Additionally, full-length BPV genomes complexed with L1 capsid proteins, possibly representing virions, have been detected in two equine sarcoids.

Cats

Feline sarcoids appear to be caused by BPV-14. As cattle are the definitive host of the presumptive causative papillomavirus, it is unsurprisingly that feline sarcoids are restricted to cats that have contact with cattle and are only seen regularly in 'barn cats' in the Midwest of the United States of America. Feline sarcoids most frequently develop on the nasal philtrum, although they can develop anywhere on the body or in the mouth. The mechanism of spread is poorly understood, but the lesion distribution suggests that biting flies or cat-fight wounds may be important for BPV-14 infection. BPV-14 is a deltapapillomavirus that is closely related to the BPVs that cause equine sarcoids. However, it is interesting that BPV-14 has not been detected in an equine sarcoid and neither BPV-1 nor -2 have been detected in a feline sarcoid. This suggests that, although the deltapapillomaviruses can cause cross-species infection, the range of species able to be infected may be limited.

Other Neoplasms

Deltapapillomavirus DNA and viral proteins, including those of types -2, -13, and -14, have been found more frequently in bladder neoplasms of cattle and water buffalo than in non-neoplastic bladder samples. While this suggests a possible carcinogenic role of the BPVs, the development of bladder neoplasia in cattle is dependent on the ingestion of bracken fern. Therefore, it cannot be excluded that the high rates of BPV detection in the bladder tumors is due to the immunosuppressive action of bracken fern, rather than because the papillomaviruses directly contribute to cancer development.

It is interesting to note that deltapapillomavirus infections of the bladder of cattle are productive and this appears to be a rare example of papillomaviruses being able to replicate in a location other than squamous epithelium. How bladder infection occurs is currently unknown. However, as papillomavirus DNA is detectable in the blood, hematogenous infection of the bladder mucosa may be most likely. Interestingly a wide range of bladder tumors are associated with papillomavirus infection including urothelial and mesenchymal types.

Pathogenesis

Papillomaviruses cause disease by stimulating increased epithelial cell replication. If there is a marked increase in replication then the infection can result in a papilloma while a more moderate increase in replication could result in a viral plaque or an asymptomatic infection. Due to their ability to interfere with the normal regulation of cell division, some papillomaviruses may influence the development of neoplasia.

Because papillomaviruses do not cause cell lysis and only produce viral antigens in the superficial layers of the epidermis, infection may elicit no immune response. If an immune response is made, it consists of the production of antibodies that protect against subsequent infection by this papillomavirus type and a cell-mediated response against cells that are infected by the papillomavirus. The initiation of a cell-mediated response is responsible for the resolution of a developed papilloma.

Diagnosis

A papillomavirus etiology of a lesion can be diagnosed by clinical examination, histology of the lesion, immunohistochemistry, or molecular techniques. Not all methods of diagnosis are appropriate for each of the types of papillomavirus-induced lesion.

Histology of a papillomavirus-induced lesion generally reveals thickened epithelium (**Fig. 5(a)**). If the papillomavirus is replicating within the lesion, papillomavirus-induced cell changes may be visible. These changes include the presence of enlarged cells with increased quantities of blue to grey slightly granular cytoplasm, cells that have shrunken nuclei that are surrounded by a clear halo (koilocytes), cells with basophilic or eosinophilic cytoplasmic bodies, cells with enlarged vesicular nuclei, or cells with eosinophilic intranuclear viral inclusion bodies (**Fig. 5(b)**). Clumping of keratohyalin granules can also be visible within the superficial layers of the epidermis.

Fig. 5 (a). Canine papilloma. The papilloma consists of marked epithelial proliferation. The papilloma is clearly demarcated from underlying dermis and the thickened epidermis is covered by increased keratin. This papilloma was caused by *Canis familiaris* papillomavirus type 1. (b). Canine papilloma. Higher magnification of the papilloma reveals papillomavirus-induced cell changes. These consist of enlarged cells with clear cytoplasm, cells with vesicular nuclei, and prominent clumping of keratohyalin granules.

Fig. 6 Papillomavirus-associated cutaneous squamous cell carcinoma from a cat. Note the intense cytoplasmic and nuclear immunostaining using antibodies against p16^{CDKN2A} protein (p16). This immunostaining pattern suggests that the behavior of the neoplastic cells was altered by papillomavirus infection.

There are two strategies that can be used to detect a papillomavirus etiology of a lesion using immunohistochemistry. Firstly, anti-papillomaviral antibodies can be used to detect the papillomavirus L1 protein. A significant disadvantage of this strategy is that L1 protein (and therefore immunostaining) will only be present in lesions that contain active viral replication and it is rare for immunostaining to be present in a lesion that does not contain papillomavirus-induced cell changes. In addition, as there are no commercially-available antibodies to most papillomavirus types of domestic species, the cross-reactivity of the antibodies is often unknown. The second strategy involves using immunohistochemistry to detect p16^{CDKN2A} protein (p16). Papillomaviruses consistently alter cell regulation by mechanisms that increase cell p16. Therefore the detection of increased p16 in a cell is consistent with the behavior of that cell having been altered by papillomavirus infection (Fig. 6). An advantage of this strategy is that p16 immunostaining will be increased regardless of the replication status of the papillomavirus in the lesion. Additionally, a commercially available anti-p16 antibody (clone G175-405) has been shown to cross react with the canine and feline p16 protein, although this antibody does not appear to cross react with the equine p16 protein. As the bovine delta-papillomaviruses cause cell proliferation by alternative pathways, increased p16 is less likely to be present in lesions caused by these papillomaviruses.

Molecular techniques available include PCR and *in situ* hybridization. PCR has the advantage of being extremely sensitive and, unlike immunohistochemistry, able to determine the papillomavirus type present within the lesion. However, as papillomaviruses often incidentally infect the skin of animals, simply detecting papillomavirus DNA within a lesion is not conclusive evidence that the papillomavirus caused the lesion. As *in situ* hybridization is able to localize the DNA within a lesion, this technique provides greater evidence that the papillomavirus was the cause of the lesion. However, as with PCR, the possibility of incidental infection cannot be excluded. The sensitivity of *in situ* hybridization is lower than PCR.

Papillomas

Papillomas are usually diagnosed by clinical examination with the presence of multiple exophytic lesions in the mouth or over the skin of a younger animal consistent with this diagnosis. Histology is rarely needed but reveals thickened folded epithelium. As papillomas are formed due to florid viral replication, papillomas are expected to contain prominent papillomavirus-induced cell changes and immunostaining using anti-papillomaviral antibodies.

Viral Plaques

Viral plaques can be suspected on clinical examination due to their appearance and location. However, canine pigmented plaques and feline viral plaques/BISCs will often require histology for definitive diagnosis. Histology of a viral plaque reveals a well-demarcated focus of mild to moderate epidermal hyperplasia that often has a scalloped appearance. The hyperplasia tends to remain superficial with little involvement of adjacent hair follicles. Cell atypia and crowding can be present, especially in more advanced feline viral plaques/BISCs. Feline and canine plaques can contain increased melanin while hypomelanosis is described as a feature of equine aural plaques. Papillomavirus-induced cell changes and immunostaining using anti-papillomavirus antibodies are variably present. Feline viral plaques/BISCs contain intense immunostaining with anti-p16 antibodies. It is currently unknown whether similar immunohistochemical changes are visible in canine or equine viral plaques.

Squamous Cell Carcinomas and Other Neoplasms

Squamous cell carcinomas are characterized by the presence of invasion of dysplastic cells through the basement membrane of the epithelium. Significant viral replication is not typically present within either SCCs or bovine bladder neoplasms and papillomavirus-associated neoplasms are not expected to contain papillomavirus-induced cell changes or immunostaining using anti-papillomavirus antibodies. There is good correlation between the presence of papillomavirus DNA and p16 immunostaining in feline cutaneous squamous cell carcinomas (SCCs), suggesting that, like human oral SCCs, p16 immunostaining may be a good indicator of a papillomaviral etiology of a feline cutaneous SCC. Additionally, p16 immunostaining was observed in a canine oral SCC that was associated with papillomavirus infection. The papillomavirus-associated cancers are expected to contain viral nucleic acids and molecular tests can be used to localize these within the lesions.

Sarcoids

Histology reveals a proliferation of well-differentiated dermal fibroblast-like cells underlying a thickened epidermis that has characteristic broad interlacing rete pegs. As these lesions support little viral replication, neither papillomavirus-induced cell changes nor immunostaining using anti-papillomavirus antibodies are present. Molecular tests can detect papillomavirus DNA, mainly within proliferating fibroblasts. In cats, as BPV-14 does not appear to infect the skin of cats asymptotically, the detection of BPV-14 from a skin tumor provides strong evidence to support a diagnosis of feline sarcoid. While the detection of BPV DNA from an equine skin mass is supportive of a diagnosis of equine sarcoid, caution has to be used as BPV DNA has been detected in skin from horses without sarcoids.

Treatment

Papillomas

Papillomas in all species typically cause little or no morbidity and are expected to spontaneously regress after a variable length of time. For the overwhelming majority of cases, benign neglect is the treatment of choice. Surgical excision, laser treatment, or cryotherapy can be used for lesions that develop in locations that cause pain or interfere with function. Papillomas can recur after surgical excision, although such warts are expected to subsequently regress once the body mounts an appropriate cell-mediated immune response. Numerous medical therapies have been proposed to hasten the resolution of papillomas. However, none has sufficient evidence of efficacy from controlled studies to be confident of any benefit. Crushing of papillomas or injecting excised papillomas back into animals (autologous vaccination) have been historically used, but is not supported by controlled studies. Likewise the use of papillomavirus vaccines has not been shown to influence papilloma regression in either humans or animals.

Viral Plaques

Viral plaques appear to only rarely spontaneously regress. As plaques are mainly a cosmetic concern in dogs and horses, they can often be left without further treatment. In cats, viral plaques/BISCs should be carefully observed due to the potential of these lesions to progress to a SCC. Treatment options for viral plaques include surgical excision, laser therapy, or cryotherapy. Imiquimod cream has been used to treat plaques in cats and horses. Imiquimod is not specific for papillomaviruses, but works by stimulating a local immune response that can cause the resolution of epidermal lesions.

Squamous Cell Carcinomas and Sarcoids

There are numerous techniques for removing these neoplasms that are out of the scope of this discussion. In cats it is possible to subdivide cutaneous SCCs into those that are associated with papillomavirus infection and those that are not. Evidence suggests that papillomavirus-associated SCCs may have a more favorable prognosis than those not caused by papillomavirus infection.

Prevention

Vaccines that contain the L1 capsid protein prevent papillomavirus infection and subsequent papillomavirus-induced neoplasia in people. This suggests that vaccination could also be used to prevent papillomavirus-induced disease in animals. However, there are some key considerations regarding the use of papillomavirus vaccines in animals.

Firstly, there appears to be little cross-protection between papillomavirus types. Therefore, vaccines would have to be created that protect against each individual papillomavirus type.

Secondly, a vaccination has to be given prior to first infection. All the papillomavirus types that are included in the human vaccines are sexually transmitted. This is critical as it can be guaranteed that people will not be infected by these papillomaviruses prior to vaccination. In the domestic species, the papillomaviruses that cause papillomas appear to most frequently infect their hosts as young adults possibly providing an opportunity to prevent infection by vaccination. In contrast, FcaPV-2, EcPV-2, and the viruses that cause canine pigmented plaques probably infect their hosts soon after birth. If so, novel strategies to allow vaccination prior to first infection will have to be developed. Additional research is required to determine when horses are infected by the BPVs that cause sarcoids.

Lastly, vaccines are likely to be expensive and it seems unlikely that a vaccine against self-regressing papillomas will be a commercial success. If papillomaviruses are found to be a key factor in the development of esophageal and bladder cancer in cattle and water buffalo then vaccination against these economically-important diseases could be viable. However, if bracken fern is found to be the major factor causing these cancers, preventing papillomavirus infection may not result in significant protection against cancer.

Glossary

Capsid The protein coat that surrounds the genetic material of a virus.

Fomite An object that can harbor pathogenic organisms and therefore may be involved in the route of transmission of the pathogen.

Subgenomic RNA (sgRNA) Viral RNA which can be directly translated into the desired viral proteins without needing to translate the entire genome. Usually translated in excess compared to genomic RNA.

T=3 Icosahedron In relation to the symmetry of virion structure, a virus with a triangulation number of 3 is composed of 12 pentameric and 20 hexameric capsid subunits for a total of 180 capsid proteins.

Transepithelial Electrical Resistance (TER) Method used to assess the barrier function of epithelial cells by measuring current passing through the cells on both transcellular and paracellular paths.

Uncoating A condition when the protein capsid of the virus is dismantled revealing the viral genome inside the host organism.

Classification

Astrovirus, a non-enveloped positive-sense single-stranded RNA virus, was first discovered in 1975 in the stool of infants suffering from gastroenteritis. The virus obtained its name after Madeley and Cosgrove noted a star-like morphology of a portion of the virions under electron microscopy. In 1993, complete sequencing of the viral genome prompted its classification to a new family to be called *Astroviridae*. The *Astroviridae* family has since been divided into two genera: *Avastrovirus*, those viruses that infect avian species, and *Mamastrovirus*, those viruses that infect mammalian species (Fig. 1). *Avastrovirus* and *Mamastrovirus* are also split into two genogroups based on of their genetic relatedness within the hypervariable capsid protein.

Fig. 1 Phylogenetic classification of *Astroviridae*. Tree generated using capsid protein amino acid sequences. Based on Ninth Report of the International Committee on Taxonomy of Viruses, 2012.

Prior to 2008, humans were thought to be infected by only eight closely related genotypes of astrovirus known as human astrovirus type 1 through 8 (HAstV1–8). These eight genotypes are now known as the classical HAstV genotypes. With the advent of unbiased full-genome sequencing and new pathogen discovery techniques, eight more novel HAstV genotypes were identified, receiving names after the location of their discovery: Melbourne (MLB 1–3) and Virginia (VA 1–5). In the same year the VA genotypes were discovered, the same viruses were discovered in samples from Nigeria, Pakistan, and Nepal. These viruses are sometimes termed HAstV-HMO due to their relatedness to human, mink and ovine astroviruses, however, for the purposes of this review will be termed HAstV-VA. Phylogenetic analysis revealed that the newly identified MLB and VA genotypes are more closely related to other mammalian astroviruses than the classical genotypes creating three genetically distinct clades of HAstV within Mamastrovirus.

Virion Structure
